The developments in automobile headlighting during the past year were characterized by structural improvements in headlamps and accessories and in the more extended use of the depressible beam system with two-filament lamps.

Among the difficulties encountered in attempting good headlighting has been the fact that headlamp construction often has been so poor that permanency of adjustment could not be expected. Also, headlamp mountings have been, in many cases, so badly designed and made that close adjustments have been difficult to obtain and when once obtained have been insecure. With respect to these matters there has been a material betterment. Furthermore, the incandescent lamps used are being made to closer factory standards, particularly with respect to positioning of the filament, (axial alinement and light center length), so that the day seems to be approaching when focusing adjustments on headlamps can safely be abolished. This will bring a great relief to the motorist and better average headlighting conditions on the road.

The belief has taken strong hold that headlight beams with a wide lateral spread below the horizontal are advantageous in night driving and the tendency is to use front glasses on headlamps which will give these wide spreads. This has brought up the difficulty that if the total available flux of light from a 21 cp. incandescent lamp is spread over as great an area as it seems to be desirable to illuminate, the beam intensities fall below a desirable limit, so that seeing is impaired. The use of the 21 cp. lamp is very extensive. In many states the use of higher candlepowers is prohibited. From a technical standpoint, however, it appears that proper illumination over the wide area which should be illuminated involves the use of higher candlepower lamps. Both the Lighting Division of the Society of Automotive Engineers Standards Committee and the Motor Vehicle Lighting Committee of the Illuminating Engineering Society, the former in connection with the preparation of the specifications for dual-beam equipment mentioned below and the latter in its last report have recognized this condition and have pointed out that the logical solution of future design involves a raising of the limit to 32 cp., a change which does not involve overloading the electrical equipment of the car.

The same committee of the I. E. S. during the past year has produced a draft of specifications for laboratory tests of optical characteristics of electrical headlamps intended to cover the so-called dual beam equipment for motor vehicles, and eventually to supersede the former headlight test specifications of the I. E. S. for the test of the single beam equipment. The Society of Automotive Engineers has cooperated in this matter and has adopted these specifications as part of its code of recommended practise. It is hoped that after a suitable trial period these specifications, with or without slight modifications, will be suitable for proposal to a sectional committee organized under the American Engineering Standards Committee procedure for adoption as an American standard.

The dual beam headlighting system discussed at some length in last year's report has been approved by all states as legal and has met with wide popularity. A large proportion of the new cars is now being provided with this equipment. By its use two things are accomplished: first, a great amelioration of the glare difficulty is obtained by the use of the depressed beam, and second, since the driving beam can be removed from the eyes of passing drivers, the adjustment of the headlamps may be such that the top of the beam is of higher candlepower than with the fixed beam equipment, thus providing a better driving light where the absence of oncoming cars renders it practicable to keep the beam in its normal position.

A promising research project directed toward the determination of the most satisfactory methods of automobile headlighting is being carried out at the Bureau of Standards under the technical direction of the Research Committee of the Society of Automotive Engineers with funds provided by the National Automobile Chamber of Commerce. The object of this investigation is to carry further by means of road tests, supplemented by laboratory work, experiments to ascertain the headlighting requirements of the driver under various conditions and how best to fulfil these requirements under definite conditions. The first part of this research, designed to show the effect on visibility distance of various road conditions and lighting distributions, has been completed. Progress is being made on the second part in which the effect of approaching lights will be considered as an additional factor.

### Signal Lighting for Traffic Control

On November 15, 1927, under American Engineering Standards Committee procedure there was approved as an American Standard a Code of Colors and Forms for Traffic Signals for Highways and Vehicles. This code includes lights used upon vehicles and also luminous signals used for traffic control, but it does not include non-luminous signs. The code establishes the use of green for GO, red for STOP, and yellow for CAUTION, and gives a scientific specification for these three colors. The code includes the type of signal to be used at railroad grade crossings to indicate the approach of a train.

The subject of non-luminous traffic signs is to be covered in a report of a committee of the American Engineering Council on Street Signs, Signals, and Pavement Markings. This A. E. C. Committee has been at work for more than a year and has nearly completed its report, which includes the choice of colors, forms, wordings, mounting positions, mounting heights, and various other details of street traffic signs as well as recommended practises for pavement markings. It is attempting to standardize the control of right and left turning movements where luminous signals are used in the hope of achieving some uniformity in the use of such signals. It favors the use of red and green only rather than red, yellow, and green; but where yellow is to be used it is hoped that it may be used in a uniform manner in all communities. Its report is now in the hands of a sectional committee of the A. E. S. C.

The A. E. S. C. code already approved provides that automobile headlights shall be white, yellow, or some intermediate hue. Tail lights are to be red and rear signaling devices are to be yellow. Other red and green lights are not to be displayed on either the front or the rear of vehicles. Conformance to this code will require the abandonment of red and green lights for route markers and for rear signaling devices.

In line with the standardization of the use of colored lights, the American Engineering Standards Committee has already approved of green as the standard color for exit lights from theaters and similar buildings.

### Sign Lighting

The National Electric Light Association, in the spring of 1928, sponsored two schools of electrical advertising which were held at the respective lighting institutes of the Edison and National Lamp Works of the General Electric Company. In addition to the technical aspects of electrical advertising, the schools stressed the necessity for cooperation between the various branches of the industry for the purpose of improving the value of this advertising medium.

The projection of advertisements upon low clouds in the sky has been made possible by the development of a huge lantern slide projector illustrated in Fig. 5. The application of this method has not as yet proved generally practicable, being decidedly limited by meteorological conditions.

The animated bulletin board type of sign consisting of figures painted with saturated colors and illuminated alternately by light of different hues continues to grow in popularity in spite of its limited color range.

Porcelain enameled steel letters are being used more extensively than in former years, particularly in connection with large roof signs. Their ability to withstand exposure to the weather and the ease with which they may be cleaned are important advantages over painted letters. The recent use of chromium-plated channel letters and borders in electric signs is one of the latest recorded developments in the sign art. The effect is apparently to multiply the number of lamps in the sign in consequence of the specular reflections from the polished surfaces. The non-corrodible quality of chromium plate renders it especially suitable for this service.

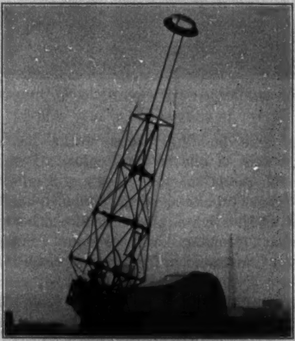

Fig. 5—Sky Projector

The increasing popularity of the neon tube is one of the notable developments in this art. It has been stated to the committee by one of the leading manufacturers that during the last four years about 700 neon electric signs have been installed in the New York metropolitan area and that more than 4500 such signs have been installed throughout the United States.

### Lighting of Building Exteriors

The floodlighting of office and public buildings has advanced rapidly during the last few years. Architects have manifested greater interest in lighting as a means of bringing out pleasing features of design and in consequence many buildings at present under construction are provided with ample wiring at the proper places for floodlighting. In the case of tall buildings the trend of practise is to light the upper stories which are visible from the greater distances and for the lighting of which facilities are afforded by the modern setback style of construction. During the past year there has been a distinct tendency toward the employment of color in floodlighting. The instances of the use of color range from small installations with touches of color here and there to large buildings whose entire facades are bathed in light of one or more colors. Perhaps the most notable recent example of colored floodlighting is the new 23-story building of the Philadelphia Electric Company which is lighted above the fifteenth story with continuously changing tints of four colors. This installation (illustrated in Fig. 6) comprises a total of 467 projectors consuming 262 kw., which is equivalent to about 9 watts per sq. ft. of lighted area. The colored lamps, which are connected directly across the line, are supplemented by clear white lamps connected in series with motor-driven dimmers. By this means the colors are diluted with white light in continuously changing proportions. The colored lamps comprise about two-thirds of the total wattage and the clear lamps one-third.

Fig. 6—Floodlighting of Edison Building, Philadelphia, Pa.

Fig. 7—Floodlighting from Ornamental Street Lighting Posts

The supply of floodlighting projectors from series street lighting circuits is an interesting development of the recent past. In this class of installation the floodlights burn on the same schedule as the street lamps, and are owned, installed, and maintained by the electric service company.

Another interesting method (illustrated in Fig. 7) of floodlighting buildings not exceeding 100 ft. in height, is the installation of projectors in the ornamental tops of street lighting posts located along the curb. In addition to the projection lamp in this type of installation an auxiliary lamp of about 200-watts rating is required in each post top in order to raise its brightness to a point where its appearance bears out its function as a light source. This type of installation has the merit of a pleasing appearance in the daytime as well as at night and is particularly well adapted to those cases where no out-of-sight location can be found for the projectors.

### Lighting of Railroad Yards

Floodlighting is becoming recognized as the standard method for the artificial illumination of railroad yards and its application is, therefore, rapidly extending. The need for more exact engineering data and method in designing floodlighting installations and selecting lighting units has been recognized. The Committee on Illumination of the Association of Railway Electrical Engineers has continued its active study of this subject, and, with the assistance of a subcommittee comprising specialists in photometric and illuminating engineering work, has prepared a "General Procedure for Photometry of Incandescent Floodlights" which it has recommended for adoption as standard practise for testing and rating floodlighting projectors.

### Railroad Signaling

During 1927 automatic signals were installed upon 5127 mi. of railroad. This record has not been equaled in any previous year. The preference for light signals is indicated by the fact that of the total number of signals installed during 1927, 74 per cent were light signals and 26 per cent were semaphore. The proportion of light signals tends to increase from year to year. Of the light signals installed during 1927, 82 per cent were colored lights, 16.8 per cent were position lights, and 1.2 per cent were color position lights. One of the outstanding developments of 1927 was the placing in service of a centralized dispatching system on the Ohio division of the New York Central Railroad. This installation represents the accomplishment of the idea of operating trains by signal indication without written train orders or operators at intermediate stations. All signals and passing side switches are power-operated and under the control of the dispatcher at a central point.

### Lighthouses

Since the first practical application of the incandescent electric lamp to large lighthouses at Cape Henry

Light in 1922, practically all of the coastal lighthouses of large size in this country have been so equipped wherever central station service is available or where a local generating plant can be maintained. During the past year ten light stations and three lightships were equipped with electricity. Small electric lights, the current for which is supplied by a battery of primary cells, are to some extent being substituted for oil burning post lights on inland rivers and similar locations. These outfits have been designed to operate without attendance for several months.

A relatively recent development in the application of electricity to the lighthouse service is the automatic lamp changing device, actuated by a no-voltage relay, which swings into focus and lights a spare lamp in the event that the first lamp burns out in operation. Though commercial types of incandescent electric lamps have been found satisfactory in lighthouse lenses of the smaller sizes, and though they produce adequate beam intensity in lenses of any size, they are not well adapted for use in large lenses designed for other illuminants because the filament is not large enough to provide sufficient vertical divergence of the beam in fixed lenses, and in revolving lenses the length of flash provided is of too short duration. Considerable experimentation along the lines of variations of filament shape and frosting of bulbs has resulted in the development of several lamps for this service which represent a great improvement over the general service types.

### LIGHTING FOR AVIATION

During 1927 much work has been done in the lighting of airways in order to promote the safety of night flying. At the present time 5800 mi. of air route are provided with flying facilities which include beacon lights 10 mi. apart, or closer where required, lighted intermediate landing fields 30 mi. apart, radio communication service for weather information and forecast, reports of arrivals and departures, and direction and control of aircraft in flight.

The beacon lights are erected on 50- or 75-ft. steel towers at the bases of which are chrome yellow arrows 56-ft. long to indicate the line of flight. The number of the beacon is painted in black on the arrow for daytime identification. The beacon light consists of three units, a revolving searchlight synchronized with two flashing red course lights. The revolving beacon has a 24-in. parabolic mirror and a 1000-watt, 110-volt T20 incandescent lamp designed to yield an average life of 500 hr. The beacon develops a beam intensity of between two and three million cp. Its axis is elevated two deg. above the horizontal and it is rotated about a vertical shaft by a motor and worm gearing at a rate of six rev. per min. Auxiliary contactors on the vertical shaft interrupt the current to the course lights according to a code by which the pilot identifies the beacon.

Each course light consists of a 500-watt, G40 incandescent lamp in a 14-in. parabolic reflector with a red or amber 30-deg. spreadlight cover glass. The electric circuits are controlled by astronomical clocks which turn the lights on at sunset and off at sunrise. Where commercial electric service is not available two-kw. full automatic gasoline engine generators are installed in duplicate. In the event of engine failure a relay places the stand-by generating unit in operation.

Intermediate landing fields are marked with a revolving beacon, a boundary lighting system, obstruction lights, and an internally lighted wind cone. The fields usually have two landing strips at right angles to each other, each about 500 ft. wide and 2000 ft. long. The boundaries of the landing strips are marked by 15-watt or larger multiple lamps in clear white refractor globes spaced about 300 ft. apart or by series lamps of equivalent candlepower. Green range lights mark the favorable approaches and 25-watt or larger multiple lamps in red globes are mounted on all neighboring obstructions.

To meet the requirements for terminal fields 425 airports have been established or are under construction by municipalities in the United States. The Department of Commerce has established an airport section to cooperate with city officials for proper selection and development of airports. Extensive tests were made during the past year in the landing of aircraft at night under varying conditions and floodlighting systems.

The outstanding developments in airport lighting during the year were a new system of grouping of incandescent floodlight units on one or more sides of the landing field, an intermediate size dioptric floodlight unit using the 5-kw. incandescent lamp, illuminated field markers and wind-direction gages and a 55-ampere high intensity arc floodlight unit with 2 deg. vertical and various degrees of horizontal spread of beam. Neon tube beacons and boundary lights have been advanced in development during the year and it is understood that in Great Britain and Germany they are employed very generally in lighting for aviation. A practical method has been demonstrated for automatically controlling landing field floodlights through switches actuated by the noise of the airplane or by a whistle of distinctive tone mounted on the plane.

### LIGHTING FOR NIGHT RECREATION

Artificial lighting is being used more and more to extend the uses of recreational areas into the dark hours. Lighting installations for night tennis, football, races, bowling on the green, hockey, horseshoe pitching (quoits), and indoor baseball are numerous and assure the practicability of night sports. Fig. 8 shows a court illuminated for playing quoits after dark. Extensive investigations at Lynn, Mass., indicate that in no very distant future the great national game of baseball may be played at night under artificial illumination.

During the past year special progress has been made in the application of artificial light to swimming pools.

In addition to levels of illumination of the order of 5 to 10 foot-candles over the entire pool area to insure safety and comfort it has been found desirable and feasible to provide, in the deeper parts, under-water illumination from units below the surface. Equipment which can be installed quite economically has recently been made available for this service.

*Christmas Lighting.* More attention has been paid to decorative Christmas lighting this year than ever before. Over fifty communities conducted contests during the holiday season in the decorative lighting of residences, all of which were successful in greater or lesser degree. Greatest interest, as manifested by the largest number of entries, has come where the contest has been divided into several classes or districts so that moderate homes were not expected to compete on an equal basis with wealthy homes. In Fig. 9 is illustrated an example of the result achieved by effort applied in this direction.

FIG. 8—ILLUMINATED COURT FOR QUOIT MATCHES

### UNDERWATER LIGHTING AND DIVING LAMPS

The standard diving lamp adopted by the U. S. Navy and approved by marine salvage companies now consists of a 1000-watt G40 extra heavy glass bulb lamp, 115-volt range, with concentrated filament construction. These lamp bulbs are tested to withstand a pressure of 150 lb. per sq. in., which suffices for submersion to a depth of 300 ft. The bulb is mounted in a housing some 18 in. long with a non-tarnishing metal reflector 11 in. in diameter. In operation the lamp bulb is in direct contact with the water, being protected only by a heavy wire screen across the mouth of the reflector. The problem of overcoming water leakage has been solved by the use of a special insulating sleeve surrounding the base of these lamp bulbs. To prevent the crushing of the lamp base and the seal, which are the weakest points of the structure, special reinforcement has been introduced. These lamps have proved very useful in recent salvage operations on the submarine S-4. Although the water near the bottom was very muddy, the divers there engaged reported good visibility at distances from 3 to 6 ft. Experiments have been conducted to ascertain whether colored light would be more effective than white light in promoting visibility under water, but the results have been chiefly of a negative character.

During the past summer underwater lamps were used in a study of tropical marine life off the coast of Haiti. Both clear and colored lamps were used and the attracting power of light for certain fish seemed well demonstrated. It is reported that electric incandescent lamps are in use as bait by Japanese fishermen.

### LIGHTING FOR AGRICULTURE

Recent investigations into the relation of light to plant growth and maturity have followed three paths, first, the relative effects of radiations of different wavelengths, second and third, the effects of variations in the relative and absolute lengths of the alternate periods of light and darkness. Different varieties of plants do not seem to react in the same way to the same conditions of irradiation. It has been reported that the growth of some plants has been stimulated and the content of certain valuable ingredients increased by exposure to the ultraviolet end of the spectrum of sunlight. Other investigators have concluded that, in general, the ultraviolet portion of the spectrum of sunlight has no great effect on plant growth, time and amount of flowering, or the weight of tissue produced. It has been observed that certain pigments, as the red in mignonette lettuce and the purple in purple cabbage, are intensified by violet and ultraviolet radiation. It has been shown by several experimenters in this field that ultraviolet radiation of wave lengths shorter than 248 millimicrons is very injurious to growing plants.

FIG. 9—DECORATIVE LIGHTING OF HOUSE FOR HOLIDAYS

Previous investigations have shown that long periods of illumination produce in some plants increased vegetative growth while in other plants they bring about early maturity. Recent experiments with the variation of the absolute lengths of the alternate periods of light and darkness (their relative lengths remaining constant) have led to the conclusion that with plants in which flowering is favored by short days, as well as with those in which the opposite is true, the general effect of relatively short alternations of light and darkness on reproductive activities is much the same as that produced by long days or continuous illumination. However, it was also observed that the short light-darkness alternations may bring about more or less serious nutritional disturbances. As the periods are shortened the plant seems to be weakened until a point is reached at which the growth begins again to improve. This point in one case was equal periods of 15 sec. of light and darkness. In another case it was found that periods of 0.004 sec. duration produced the same rate of assimilation in the plant as did continuous illumination.

The attraction of light for insects has been used for many years in luring them to their destruction. A recent application of this principle was made in Alabama where fruit worms had caused severe losses in the tomato crop. With 100- and 200-watt lamps and flat reflectors suspended 5 ft. from the ground and over pans of water covered with kerosene, the protection was reported to be so complete that only 35 worm-infested tomatoes were found in two acres, whereas neighboring unprotected fields suffered losses from 30 to 50 per cent.

That color is a factor in the attraction has been shown in some results obtained at the State Experiment Station at Geneva, N. Y. It was found that "tent caterpillars," a most ravenous insect pest, would leave young apple twigs and gather in places where there was plenty of light though little fodder. With differently colored lights, the apparently hungry caterpillars usually went directly to those of a pale yellow. Some preferred a deeper yellow, but red light appealed to only a few.

From other quarters information has been received that while many experiments, some of them very careful tests, have been made with lights in the control of different insect pests such as the cotton worm, cotton boll weevil, codling moth, Japanese beetle, etc., the results have not been sufficiently favorable to indicate that any material help may be expected from the use of light traps under the conditions of experimentation. It is believed that there is room for considerable further experimentation in this field, as with lights of different colors and different intensities.

The use of artificial light in poultry houses during the winter months has become a common practise on many poultry farms. The usual method is to turn on the lights for a short period morning and night in order to extend the period of daylight, thus stimulating the activity of the hens and increasing their food consumption and egg production. In addition to the use of artificial light in this connection, electricity is being used in experimental work to furnish ultraviolet rays to young chicks and also to laying hens which are kept confined where they do not get direct sunlight, the effect of the ultraviolet radiation being to promote bone formation and to prevent the occurrence of leg weakness, a condition resembling the disease in human beings known as rickets. The more common practise, however, is to accomplish this result by administering with the chickens' feed a ration of cod liver oil which has the same specific effect as ultraviolet radiation.

## Other Topics

### SOURCES AND APPLICATIONS OF ULTRAVIOLET RADIATION

The general interest in the health promoting use of ultraviolet radiation has stressed the need, on the one hand, for windows transmitting all of the sun's short wave radiation, and on the other hand, for artificial sources emitting little or no radiation of higher frequency than that present in direct sunlight. The former need has been met by a variety of more or less satisfactory materials for use in place of ordinary window glass. Of these materials the degree of transparency to ultraviolet radiation varies greatly. Moreover, the transparency of certain materials tends to deteriorate with exposure.

The latter need arises from the hazard incidental to the use by laymen of the high intensity, high frequency ultraviolet sources formerly used only by the medical profession, and also from a recent tendency to attribute the maximum therapeutic value to those wave lengths in the immediate neighborhood of 300 millimicrons. This need has been met by the use of the new window glasses as filters in connection with arc lamps which have long been used as artificial sources of ultraviolet radiation. However, much attention has been given to the problem of developing a new source characterized by a maximum possible emission in the region from 280 to 320 millimicrons, with no emission of shorter wavelength and a minimum of radiation of longer wave length. It is expected that such a source of ultraviolet radiation will appear on the market within the next year.

The types of artificial sources at present available are being widely sold for use not only by physicians but for home use under medical supervision. Artificial "solariums" are being generally established in connection with athletic clubs, Y. M. C. A.'s, Y. W. C. A.'s, and sanitariums throughout the country. Baby clinics primarily for ultraviolet treatment and prevention of rickets are in operation in many large cities.

Two new industrial applications have been well established during the past year. The application of ultraviolet radiation from artificial sources to the hardening of the varnished surface of patent leather has been successful in effecting a higher quality of product with a much shorter treatment than was possible by the former method of exposure to sunlight. The exposure of dried milk powder to ultraviolet radiation has resulted in the production of an infant food having marked antirachitic properties. A similar use of ultraviolet radiation in connection with the preparation of other food materials is under investigation.

### PHOTOMETRY

Recent progress in photometry has taken the form of refinement of existing methods and instruments and of increased knowledge of the characteristics of the photoelectric cell. The advent of the four element vacuum tube has made it possible greatly to improve the sensitivity, speed, and precision of photoelectric spectrophotometry. The photoelectric cell containing a monomolecular layer of caesium which has recently become available, represents a distinct advance over the earlier types in stability of color sensitivity and in approach to eye sensitivity.

A recent development in the photometry of floodlights and other projectors has been the use of a concave spherical mirror in place of a diffusing hemisphere for integrating the light flux over a unit of solid angle.

The standard method for photometry of floodlighting projectors, mentioned elsewhere in this report, which has been formulated by the Committee on Illumination of the Association of Railway Electrical Engineers, is intended to render possible the comparison of results of photometric tests made on projectors by different laboratories. This is achieved by standardization of testing conditions and methods of computation of results from test data. Briefly, the method provides that the light flux within a solid angle of one square degree be measured in an integrating device at a distance of not less than 100 ft. Observations are taken at approximately 100 stations uniformly spaced throughout the beam, and in addition, at a series of stations on eight equally spaced lines radiating from the axis of the beam and extending to the limits of the lighted area. This method of integrating the light output over a solid angle of one square degree minimizes erratic results due to traces of filament image in the beam. Since the beam limits are defined in terms of the maximum candlepower value, individual test results of single projectors show some variation in beam efficiency. Further refinement of the method is under consideration with a view to reduction of these variations.

The great differences in the intensities and the spectral characteristics of the ultraviolet radiations from the various sources make it desirable to be able conveniently to compare the radiations from several sources in terms preferably of some standard unit of intensity. Unfortunately no convenient method of accomplishing this has been standardized, though it has been suggested that the intensity of the ultraviolet component of sunlight at least may be inferred from photometric measurements, the factor of proportionality having been determined for the given locality by radiometric measurements in the laboratory.

### MISCELLANEOUS APPLICATIONS OF LIGHT

An interesting and novel application of light is in a device recently developed for measuring the change in length of a small specimen of magnetic material upon magnetization. This change of length is of the order of a billionth of an inch. In this apparatus the image of an illuminated portion of a ruled grating is reflected back upon another portion of the grating by a pivoted concave mirror which is arranged to tilt slightly when the length of the specimen changes. Behind the second portion of the grating is a photoelectric cell. As the mirror tilts the image moves across the grating, causing a variation in the amount of light transmitted to the photoelectric cell. The response of the cell, as indicated by a sensitive galvanometer, is a measure of the tilt of the mirror and of the change of length of the specimen.

A recent application of ultraviolet radiation and the photoelectric cell is in a device for the automatic concentration of ores. The crushed raw ore on a belt passes under a source of ultraviolet radiation which causes the pieces of valuable material to fluoresce strongly, while the pieces of worthless rock remain unaffected. A photoelectric cell screened from the ultraviolet radiation picks up the visible light of the fluorescent material and actuates a device which separates this material from the rock.

### INTERNATIONAL CONSIDERATION OF ILLUMINATION TOPICS

The occasion of a plenary meeting of the International Commission on Illumination in America will be marked by an International Illumination Congress during the week of September 24, 1928. In addition to reports of technical committees of the I. C. I., there will be papers and discussions on a variety of lighting topics. This meeting is expected to bring together leading lighting experts from the several countries and bids fair to advance understanding through the exchange of technical information with results beneficial to all participating countries.

# Electrochemistry and Electrometallurgy

## ANNUAL REPORT OF COMMITTEE ON ELECTROCHEMISTRY AND ELECTROMETALLURGY*

*To the Board of Directors:*

The Committee on Electrochemistry and Electrometallurgy makes its annual report as follows:

The revision of the Institute's standards for storage batteries which was proposed by this committee several years ago has been completed by Working Committee No. 37. The revised standards were adopted by the Board of Directors February 16, 1928 and have been published.

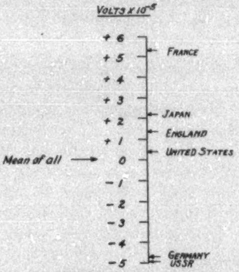
Standards for the international electrical units continue to receive attention at the National Standardizing Laboratories. These standards are the basis for electrical measurements of both the engineer and the physicist. The standards for the international system of units are essentially electrochemical and it is appropriate, therefore, to review briefly the present situation in regard to them. Since 1911 fundamental measurements of current have been based upon wire resistances and the value determined for the Weston normal cell by an international technical committee which did its experimental work in Washington during the year 1910. At that time values to be assigned to the wire resistance coils were agreed upon. No detailed specifications for either the standard cells or the silver voltameter which serves as the international standard for the measurement of current were agreed upon, but the work of preparing such specifications was continued by several of the national laboratories until interrupted by the War and a high degree of uniformity was attained in the voltameter measurements.

The interlaboratory comparisons of standard cells were also interrupted by the War and it is only within recent months that we have obtained comparisons of the value of the volt in the principal countries. Direct exchange of standard cells has been made between the Bureau of Standards and several foreign laboratories. Several groups of cells have been taken also to the various national laboratories by representatives of the Central Chamber of Weights and Measures at Leningrad. A report by M. Malikoff and M. Kolossof has recently communicated the results of their comparisons. On the basis of their report as well as the direct exchange of cells, the accompanying figure has been prepared to show the relation of the volt in six countries at the present time.

The maximum differences are rather larger than was to be expected. This should not be interpreted as meaning that the saturated cell is not reliable or reproducible since the value for the cell is a derived value and may therefore include uncertainties in the value of the ohm or errors in the use of the voltameter, or whatever other means may have been employed for determining the cell values from time to time.

The procedure for maintaining the volt by means of the Weston normal cell at the various laboratories differs very greatly. A redetermination of the international ampere by means of the silver voltameter has been undertaken by the Bureau of Standards. Work of this character has not been done previously for 15 years.

Whatever the outcome of the present discussions as to the advisability of continuing the international system of electrical units or changing to the absolute, c. g. s. system may be, the maintenance of the reference standards, particularly the standard cell and the wire standards for resistance will be none the less important. If the absolute units are eventually adopted in place of the present international system, the silver voltameter and the mercury ohm will be discarded.



RELATIVE VALUE OF THE VOLT IN SIX COUNTRIES AT THE PRESENT TIME

The fifty-third meeting of the American Electrochemical Society included a symposium on the chemical production of electricity. Eighteen papers were presented on primary cells, storage batteries, rectifiers, and electrolytic condensers. The feasibility of making dry cells without the use of manganese ore was described in several papers. Graphitic oxides have become a commercial possibility as a substitute for manganese dioxide, but no immediate change in the construction of dry cells is likely. The graphitic oxides, however, should find other applications where a convenient source of loosely held oxygen is needed. The absorptive properties of finely divided carbon have also made possible the construction of primary cells of large capacity, subject only to the renewal of the zinc and the electrolyte.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

The development of satisfactory aluminum electrolytic condensers has been important in the telephone field. These condensers have a service life yet to be determined. Some have been in service more than five years and others, operating under test conditions in the laboratory, have passed eight years. The capacity depends somewhat on the formation and the conditions of service. Condensers for 24-volt circuits have a nominal capacity of 1000 $\mu$ f. and weigh about 40 lb.

An electrical distillation method described in a recent paper before the Electrochemical Society has been developed for the manufacture of chemically pure hydrochloric and nitric acid. By this means a continuous process has become possible, utilizing electrical energy in place of fuel, with added advantages of greatly reduced cost and an improved product.

Electric melting of steel and iron has maintained its already established position. Complete data are not available on furnace installations during the past year, but a considerable number of new installations include the 'Lectromelt furnaces. The United States is believed to lead the world in the production and utilization of the electric furnace. One noteworthy installation for which an order has been placed during the early part of 1928 is for a 60-ton steel-melting furnace to have an installed transformer capacity of 20,000 kv-a. The phrase "electric steel" has now become a trade mark of superior quality.

Increasing interest has been noted in the possibility of providing greater uniformity in composition and physical properties of cast iron and this affords a promising field for electric furnaces.

The induction type of furnace, sometimes referred to as the high-frequency furnace, has appeared in the ferrous field for the production of alloy steels. In the past, the opinion has been held that the induction furnace would not be useful in the iron and steel industry although it had found a place for itself in the nonferrous field. At the present time some are inclined to think that the widest application for the induction furnace will eventually be in the iron and steel industry. The design of a one-ton steel melting furnace of the induction type is now in the development stage. During the past year new installations have been devoted largely to the manufacture of high-grade special steels and alloys.

Another development in the electric furnace field has been the introduction from France into this country of the Miguet electric furnaces. Electric furnace engineers have recognized the desirability of using large electrodes in order to produce more efficient operation and better quality of production. The electrode in the Miguet furnace covers the entire molten charge, that is, the diameter of the electrode is equal to the diameter of the bowl.

Electric melting in the brass industry is a development of comparatively recent years but it has now become firmly established by affording a control of the product that was previously lacking and by improving working conditions. The smaller brass foundries have been somewhat slower in adopting electric heat for melting than the larger plants in the wrought brass industry, but relatively small furnaces of the single-phase type are now becoming more common.

Increased interest has been shown in the wide application of electric furnaces to various other industries and of particular note is the recent application of electric furnaces to glass melting. This has been a difficult problem to which extended research has been devoted and it is only recently that practical installations have been made. The glass charge is used as the resistor.

Industrial electric heating and annealing has continued to advance. Recent conferences on this subject have been held at Purdue and Yale Universities. A notable example of electric heating and annealing has recently been carried out at the Bureau of Standards in connection with the cooling of the largest disk of optical glass ever cast in America. Refractories for furnaces used in the glass industry have been improved during the year by the introduction of Corhart cast refractory blocks. These are made by fusing aluminous silicious material in an electric furnace and then casting the material in blocks at a temperature about 1900 deg. cent. This material on cooling has a dense interlocking crystalline structure which is nonporous. Tests which have been made in the glass industry show that it has much longer life than any other refractory previously used in that work.

Among the resistors for furnaces, there has been further development in what is known as the Globar elements. These elements are made of silicon carbide. The idea of using this material as an electrical resistor in high temperature work is not new, but it has not been used extensively until recently. Silicon carbide has a large negative temperature coefficient and when used as a resistor was not entirely stable. That is, its resistance tended to increase after a short period of use. During the past year a much more stable resistor of this type has been made and these are now obtainable in large sizes, some as large as 2½ in. in diameter and 5 ft. long with an electrical rating as high as 25 kw. per bar. Another difficulty with these resistors has been overcome by a method developed within the past year for improving the electrical contact at the terminals.

Chromium plating continues to be the center of interest in the electroplating field. Clearing of the patent situation will doubtless further stimulate the use of this metal in electrodeposition. One of the most interesting developments during the past year has been in connection with chromium plated tools. The industry has reached a stage where the demand for chromium plated-ware is far in excess of the supply.

Cadmium plating is proving valuable as a preventative of rust and its use is growing on this account.

Many attempts have been made to develop satisfactory methods of electroplating aluminum and its alloys, but few of these hitherto described have been successful. Adherent smooth deposits of nickel and other metals on a roughened aluminum surface have now become possible by methods recently described to the Electrochemical Society. These methods vary in detail and are adapted to pure aluminum as well as to each of a number of its alloys. The plated aluminum has advantages by reason of its improved appearance as well as its resistance to abrasion.

The Copper and Brass Research Association has been instrumental in making the uses for copper and brass better known to the public. Evidence of this is found in the fact that the use of brass pipe has increased over 200 per cent in the last three years. The older copper refineries are said to be planning extensive modernization programs chiefly along the line of reducing the power cost.

The output of electrolytic zinc continues to grow as a result of available cheap zinc concentrates which can be handled by this method. This affords a valuable outlet for electrical energy which is likely to increase. The output of electrolytic zinc from aqueous sulphate solution is estimated at the present at 500 tons a day as compared with 100 tons at the close of the War. An increased capacity for the production of electrolytic zinc is forecast for the coming year as several large electrolytic plants have recently been built or projected and some chemical engineers say the time is not far distant when virtually all zinc will be electrolytically refined, as in the case of copper, because of the better quality of the product. The development of the de Laval electrothermic process in Sweden by American interests may, however, have an important result in this field.

In the lead field, additional Betts plant capacity is being built and it seems possible that the demand for lead which is very low in bismuth may become more general. At Kellogg, Idaho, and in Peru, the Tainton process of recovering lead electrolytically from leach liquors along lines analogous to the zinc work is in development.

In the field of aluminum and its alloys a new form of sheet material combining the strength of the alloy and the resistance to corrosion of pure aluminum has recently appeared under the name, Alclad. This consists of a heat treated aluminum alloy base with a smooth nonporous surface of pure aluminum alloyed to the core. This material is expected to overcome serious difficulties which have been experienced with aluminum alloys in the past. Magnesium is finding increasing use in the aluminum alloys of high strength. Uses for the very pure aluminum prepared by the Hoopes process are increasing.

The chief interest in the production of metals from fused electrolytes has recently centered around the large aluminum plant now being constructed at Arvida, Canada. The capacity of this plant is planned to equal the present world production of aluminum. Two sections of the plant have been put in operation. The construction of all-metal airplanes is expected to be an important factor in providing an outlet for the greatly increased production of the light metals.

Beryllium has risen to a position of importance among the metals produced from fused electrolytes. Three per cent of Beryllium added to iron produces a steel and an equal quantity added to copper makes a valuable bronze. Rare metals are being produced on a limited scale by the electrolysis of fused salts and of these the most notable is probably Zirconium.

The use of electrolytic hydrogen in the production of synthetic ammonia has been increasing. Several large installations are planned for this year in Japan and Norway. One of the objections in the past to the electrolytic manufacturing of oxygen has been the lack of a market for the byproduct, hydrogen. The use of atomic hydrogen in welding operations promises a possible balance to make possible the economic production of electrolytic oxygen and hydrogen in place of liquification equipment now used for making oxygen alone.

A new type of oxy-hydrogen cell has recently been designed to operate at high temperatures without undue deterioration. The larger cells are rated for 2.3 volts at a maximum current of 15,000 amperes. These cells are said to be able to follow the normal load in somewhat the same way as the storage battery when charging at a variable rate and to do this without any great change in efficiency. Off-peak energy converted to direct current can be absorbed with a consequent improvement in load factor and it is claimed that the cells may be operated on 3300-volt circuits. It is suggested that under some conditions the large scale production of these gases at a low cost might reach a point where they could be used in the production of gas for heating purposes.

The materials for nitrogen fixation are so universally available that the problem of nitrogen fixation and the use of the products for fertilizer, munitions, or otherwise is largely a problem of national requirements, as to which each nation can reasonably hope to be independent. The development of nitrogen fixation, however, depends on the economic conditions and is in the line of decreasing cost of production wherever possible. Electric power is not available cheaply enough to make the arc process a likely competitor of the other processes. The synthesis of ammonia is developing most rapidly at present.

The great development in small rectifiers of the electrolytic type which was noted several years ago in the radio field has been checked by the recent development of a-c. radio sets and the so-called dry or electronic rectifiers. Valuable information as to the details of improvements made in the aluminum rectifier as well as other types have become available. Mechanical rectifiers for high-voltage alternating current have been displaced by the vacuum tube.

In the field of electrochemistry of gases, outstanding developments are largely the researches of Dr. Lind and his associates who have been able to produce reactions at low temperatures without use of high voltages by exposing the gases to the emanations from radium. Similar work has been done by Daniels and others on the synthesis of ozone and nitric oxide by the use of high-voltage cathode rays. The use of ozone for the purification of drinking water has trebled within the past few years.

Outlets for electrical energy in various industries that have not previously made extended use of electricity are significant. In the paint, varnish, and lacquer industries the electrolytic production of lead carbonate is increasing. The synthetic preparation of acetic acid, acetone, and methyl alcohol in which electrolysis may play a part, has had an important effect in replacing products formerly obtained by wood distillation.

The heavy clay industry has made progress in the use of electrical machinery but is still behind in the development of such lines. Brick manufacturers are beginning to realize the advantages of electricity as a means of saving labor and the proper control of the products.

On all sides we find a constantly increasing demand for new products to meet conditions which were unknown in the past. Everywhere there is an increasing interest in the work of the research laboratories and the demand for greater results from research people.

The committee wishes to acknowledge valuable suggestions for the preparation of this report which have been made by Prof. C. G. Fink, secretary of the American Electrochemical Society.

George W. Vinal, *Chairman.*

# Electrical Machinery

## ANNUAL REPORT OF THE COMMITTEE ON ELECTRICAL MACHINERY[*]

*To the Board of Directors:*

At the beginning of this year, the Electrical Machinery Committee adopted a new plan of organization, comprising apparatus subcommittees to deal with matters in their respective fields, and, in addition, two general subcommittees, one responsible for the preparation of the annual report and the other responsible for the review of papers submitted to the Institute.

Each apparatus subcommittee has dealt with such matters as the initiation of papers, collection of information for use in the annual report, the development and publication of useful information, and the initiation and preparation of Institute standards in cooperation with the Institute Standards Committee.

Five apparatus committees have been organized during the year as follows: Transformer with W. M. Dann, Chairman; Synchronous Machinery, W. J. Foster, Chairman; Induction Motors, P. L. Alger, Chairman; D-c. Generators and Motors, A. M. MacCutcheon, Chairman; Mercury Arc Rectifiers, B. G. Jamieson, Chairman.

The chairman of each subcommittee has organized a committee whose membership has included members from the Electrical Machinery Committee and members from the Institute at large. While the membership of the Electrical Machinery Committee has been somewhat smaller than in previous years, there has been no limit placed upon the size of the several apparatus subcommittees. Each chairman has changed and increased the membership of his subcommittee as the nature of the work to be done has changed and increased.

The general committee on the annual report has consisted of C. W. Kincaid, chairman, and the chairmen of the various subcommittees. While the chairman of the annual report subcommittee has been responsible for the preparation of the annual report, he has looked to the chairmen of the several apparatus subcommittees for material within their respective fields.

The general subcommittee on meetings and papers has been headed by the chairman of the main committee, and he has called upon the entire membership of the committee for help in reviewing papers submitted by the Institute's Meetings and Papers Committee.

According to this plan of organization, the work of the committee has been subdivided among the various subcommittees, and whatever has been accomplished by the Electrical Machinery Committee has been due to the initiative, sense of responsibility, and hard work of the subcommittee chairman. The chairman of the main committee wishes to take this opportunity of acknowledging the value of its work and expressing his appreciation of the large measure of responsibility they have assumed.

The committee has held two general meetings during the year—one in October and another in February during the Winter Convention. In addition to these general meetings, the various subcommittees have held separate meetings as required by their programs. In general, the detail active work of the committee has been accomplished through the meetings and other activities of the subcommittees.

The transformer subcommittee under the chairmanship of W. M. Dann has completed very important work in connection with transformer standards. An appendix to Transformer Standards, Section 13 of the Institute Standards, has been agreed upon and submitted to the A. I. E. E. Standards Committee for their consideration and action. This appendix covers recommendations for the *operation* of transformers by total observable temperature, and permits the operation of transformers at loads greater than the rated load providing the temperature of the cooling medium is below 30 deg. for air or 25 deg. for water.

The transformer subcommittee has also had in preparation recommendations for standards of constant-current transformers. This work has been done under the immediate direction of H. C. Louis.

The synchronous machinery subcommittee, under the chairmanship of W. J. Foster, has cooperated with the Institute's Standards Committee and with the Sectional Committee of the A. E. S. C. in the revision of Section No. 7 of the Institute Standards. This subcommittee has in preparation recommendations for standards on capacitators.

The subcommittee on mercury arc rectifiers, B. G. Jamieson, chairman, has been particularly active in initiating standards for this new type of apparatus and in collecting information concerning the application and operation of rectifiers in this country and in Europe.

During the year, 17 papers have been presented under the auspices of this committee at the general and regional meetings of the Institute. These papers and the discussions resulting therefrom have made valuable contribution to design information on such subjects as the reactance of synchronous machines, turbine generators, magnetic leakage and fringing flux, eliminating corona around armature coils of high-voltage machinery, methods of measuring cooling air, heat losses in the conductors of d-c. machines, excitation systems, and to the application information of two-pole synchronous motors, large frequency changers, etc.

*Presented at the Annual Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

The following review of progress during the past year has been prepared by the various subcommittees having jurisdiction over the particular machinery involved under the general direction of C. W. Kincaid. An attempt has been made in this report to include the more important articles that have appeared in domestic and foreign journals. These appear in several bibliographies and there are undoubtedly articles of real merit which have been overlooked. The committee will welcome having such omissions brought to its attention. A new plan has been initiated in connection with the bibliography in this annual report. It has been the endeavor to include all important articles and papers published during the calendar year of 1927 and, in addition, the outstanding papers that have been published in 1928 up to the time of publication. Next year's report will give a complete bibliography for 1928, repeating the more important references included in this report. By this plan the complete bibliography will be for calendar years (thus agreeing, as to dates, with the bibliographies prepared by leading libraries) and in addition, recent important articles and papers will be included.

### TRANSFORMERS

Very few engineers, with the exception of those intimately connected with the design of transformers, realize the remarkable changes that have been made in the design requirements during the last five years. With this in mind, we attempt to review in this report the factors that have brought about these changes and to show their effect on the developments of the past year.

These factors have been brought about by the natural growth and the changing requirements of the electrical industry which are due to the increase in capacity of power plants and substations, the extension of high-voltage transmission to higher voltage and greater power concentration, and the development of what can be properly termed high-voltage distribution networks.

These changes are responsible for the further development of the load ratio control transformer, the multi-winding transformer, and the varied winding auto-transformer. Such a unit not only steps up and steps down the voltage, but is frequently the meeting point of three or four voltages on the network, thus requiring three or four windings instead of two. Modern conditions also require that the voltages on various parts of a network be varied with the load. Thus it is no longer correct to speak of a "static" transformer. Gears, tap changers, and interlocking and remote control devices have been added for giving out and taking up the voltage slack of the system automatically as the load requires.

Then, too, the high-voltage distribution has resulted in many transformers with secondary windings of relatively high voltages. The 33-kv. secondaries have been quite common for some years. Now 66-kv. secondaries are often called for. Units are being built for 132 or 220-kv. to 66-kv. Even 110-kv. secondaries are appearing, and a bank with 140 kv. on both primary and secondary with load ratio has been built. This condition of having both windings at high voltages, of course adds to the physical size of a unit for a given kv-a. and since taps are frequently required in the secondary winding, they add to the difficulty of designing the unit.

There is one other factor that is of sufficient importance to mention. This high-voltage distribution with its increase in length of feeders has resulted in requirements for greater tap range in voltage due to the higher reactance of the feeders. Thus the customary 10 per cent range in voltage is no longer adequate for every condition, and tap ranges from 15 per cent to 20 per cent are being specified by some operators. This requirement adds to the size of the transformer and unbalances the design for it is practically impossible to maintain a balanced arrangement of the windings with respect to one another, except on one voltage connection. The unbalance increases with the tap range. Thus the larger the tap range, the greater the unbalance, the greater the change in reactance, and the greater the increase in short circuit forces.

### EQUIPMENT FOR CHANGING TAPS UNDER LOAD

The report for 1926 describes in detail two methods of tap changing under load; namely, the two winding and the single winding arrangements.

During the year 1927, a large number of power transformers has been supplied with equipment for changing taps under load, with the ratio of the transformers changed by changing the voltage of a series transformer excited from a third winding on the core of the power transformers. This method permits the application of low-voltage tap changing equipment to high-voltage delta-connected windings and to high-voltage star-connected windings which are not grounded or to be grounded through a resistance.

Fig. 1 is a typical diagram of connections for this method of tap changing. A series transformer is connected in series with the winding whose voltage is to be regulated. One side of the primary of the series transformer is connected to the midpoint of the regulating winding, the other side of the primary winding being switched along the taps of the regulating winding by means of the tap-changing equipment. The familiar single-winding method is used for changing taps of the regulating winding. When power transformers are supplied with a third low-voltage winding for power purposes, taps can be placed on this third winding for use with the tap changer at only slight additional expense.

Three of the 10,000-kv-a. transformers shown in

Fig. 2 are used in a bank to transform 30,000 kv-a. from 140,000 to 140,000 volts, with equipment on one side for changing taps under load. Oil-immersed contactor switches are used to change taps by the single-winding method. Since the high-voltage winding whose voltage is regulated is connected in delta, a series transformer is connected inside the delta and is excited from a low-voltage tertiary winding. The tap-changing equipment is placed in the low-voltage winding.

FIG. 1—SCHEMATIC DIAGRAM OF CONNECTIONS FOR CHANGING TAPS UNDER LOAD, USING A SERIES TRANSFORMER IN THE WINDING WHOSE VOLTAGE IS TO BE CHANGED AND THE REGULATING WINDING IS A THIRD WINDING ON THE SAME TRANSFORMER

What is thought to be the world's largest self-cooled transformer has recently been completed. It is rated at 33,333 kv-a., 220,000 volts star, to 69,000 volts star, to 13,200 volts delta. Seven of these units (one a spare) will be used to form two 100,000 kv-a. transformer banks at the Plymouth Meeting substation of the Philadelphia Electric Co. Power generated at the new Conowingo hydroelectric plant will be stepped down from 220,000 volts through these banks for transmission through the present 69,000-volt Philadelphia system. The 13,200-volt windings will supply two 44,000-kv-a. synchronous condensers for line regulation.

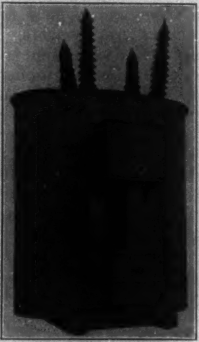

FIG. 2—10,000-KV-A. POWER TRANSFORMER—60 CYCLE—SINGLE-PHASE—140,000/140,000 VOLTS, WITH LOAD RATIO CONTROL EQUIPMENT MOUNTED ON THE SIDE. CONNECTIONS AS SHOWN IN FIG. 1, WITH OIL IMMERSED CONTACTORS ARE USED

These transformers while rated at 100,000 kv-a. per bank have three separate windings, with equivalent parts somewhat higher. With auxiliary cooling on the radiators, which is contemplated in the future, the equivalent two-winding loading which the transformers will deliver with low ambient temperatures is 200,000 kv-a. per bank.

Each transformer complete with oil weighs 180 tons and occupies approximately 500 sq. ft. of floor space. Some idea of the height of the tank is obtained by the fact that a six foot man can stand underneath the fourteen foot radiators as they are mounted on the tank. The height over the high-voltage bushing is 31 ft.

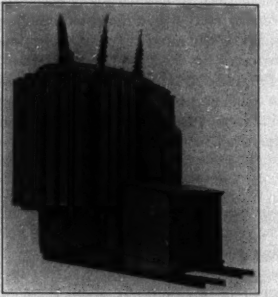

FIG. 3—33,333-KV-A. POWER TRANSFORMER—60 CYCLE—SINGLE-PHASE—220/69/13.2 KV. WITH LOAD RATIO CONTROL FOR THE 69-KV. WINDING

The construction used made it possible to ship the transformers in oil to their destination, notwithstanding the large capacity and high voltage.

These transformers are provided with equipment for changing the voltage ratio of the middle voltage winding by means of tap-changing equipment located in the low-voltage winding. Only one extra tap is necessary for the tap-changing equipment, as the low-voltage taps, which are used for the starting of the synchronous condensers are used for the tap-changing equipment. The single-winding method of tap-changing is used, with a type *UB* tap changer and preventive auto-transformer and series transformer. The preventive auto-transformer is switched along the low-voltage taps by means of the circuit breakers of the type *UB* tap changer. The midpoint of the preventive auto-transformer and the midpoint of the low-voltage winding are connected to the primary of the series transformer, the secondary of the series transformer being connected in series with the middle-voltage winding to give a voltage regulation of 15 per cent in six 2½ per cent steps. Fig. 3 shows this transformer and equipment.

Fig. 4 shows a 10,000-kv-a., single-phase, 35,000-volt transformer arranged for 20 per cent regulation, using a new type of tap changer of the single-winding method. Fig. 5 shows the scheme of connections in which the series transformer is connected in the line to be regulated and the primary of the transformer is excited from a low-voltage winding which in turn may be excited from any of the transformer windings. Only two tap-changing circuit breakers are used, an auxiliary oil-immersed tap-changing switch being used to do the actual tap-changing. One of these transformers is arranged for complete automatic control in response to fluctuation of the system voltage.

designed to be applicable to larger kv-a. transformers merely by the substitution of larger kv-a. regulators, and is built for future addition of automatic control which is responsive to voltage fluctuations of the system. Fig. 7.

### THE INERTAIRE TRANSFORMER

In addition to the 33,333-kv-a. transformers for Philadelphia Electric Co., four 33,333-kv-a., O. I. S. C. Inertaire transformers for Southern California Edison Co. have been built. These transformers will be installed in a 100,000-kv-a. bank, with a spare, at Long Beach Steam Plant No. 3, to operate on a 220-kv., three-phase, 50-cycle system transforming from this voltage to 16,500 volts on the low-voltage winding.

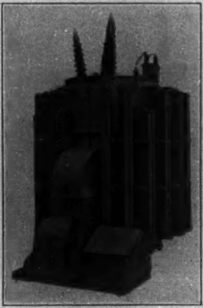

FIG. 8—33,333-KV-A. INERTAIRE POWER TRANSFORMER 220,000/16,500 VOLTS, 50 CYCLES. EQUIPPED WITH AUXILIARY AIR COOLING ON THE RADIATORS

These transformers are two-winding units arranged with detachable radiators equipped with duct for air blast. Complete with blower equipment these units will each weigh approximately 98 tons and occupy a floor space of 360 ft. Over-all height from rail to bushing tip, approximately 32 ft. They will carry 60 per cent normal load continuously with an ambient of 40 deg. cent. without exceeding 55 deg. cent. when the blowers are not in operation. Blowing equipment is individual and mounted on separate base with wheels. By opening the duct at one point, complete blower equipment can readily be moved away from the main units.

The motors for this equipment are of the across-the-line starting characteristics. All motors, including spare unit, are arranged to be started and stopped together by relay actuated by temperature conditions inside the main transformer. These transformers are shown in Fig. 8.

In the Inertaire transformer, the breathing regulator allows in-breathing at a slight vacuum but prevents out-breathing until a pressure of 5 lb. is developed in the transformer tank. Thus there is a definite relation between the amount of initial gas space required and the change in oil volume to keep the transformer from breathing.

With small transformers this relation can be obtained with a reasonable initial gas space, but as the size of the transformer increases, with its consequent reduction in gradient between copper and oil, it becomes desirable to decrease the amount of breathing by providing additional gas space to supplement the volume above the oil level.

During the past year it has become customary to supply on all large transformers some additional gas space other than that above the oil, in order to cut down the amount of breathing of the transformer. This decrease in breathing reduces considerably the cost of maintenance of the Inertaire equipment for the chemicals of the Inertaire jars are used up in proportion to the amount of breathing which takes place.

Several methods are used to obtain this additional gas space.

The general practise, as shown in Fig. 9, is to place gas chambers beneath the oil level between the iron core and the tank. These are crescent-shaped compartments welded to the tank wall with or without a space between, depending upon the type of transformer. In a few cases ordinary expansion tanks have been supplied, filled with an inert gas and connected to the gas space in the transformer tank. These act as gas chambers and cut the breathing of the transformer down to a minimum. Another type of gas chamber consists of connecting a spare tank to the gas space of one or more transformers, and this auxiliary space provides the necessary gas space to prevent the transformer from breathing. In this way the maintenance cost of the Inertaire transformer in extremely large sizes which ordinarily breathe large volumes of air has been greatly reduced.

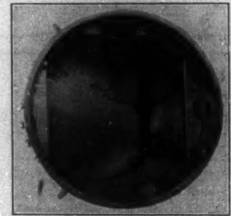

FIG. 9—INTERNAL TANKS TO PROVIDE MORE SPACE FOR EXPANSION OF INERTAIRE AND THUS REDUCE THE AMOUNT OF BREATHING

There are approximately 85 different operating companies now using Inertaire transformers, with a total Inertaire transformer capacity of about 5.5 million kv-a. in service.

### DISTRIBUTING TRANSFORMERS

During 1927 a number of three-phase, 60-cycle, O. I. S. C. manhole transformers of 300- and 450-kv-a. capacity were built. These transformers take power at approximately 11,000 volts, delta, and supply the low-voltage network at 199 volts star with a permanently grounded neutral for four-wire operation.

Each transformer is fitted with the usual thermometer, oil-gage, drain, filter and sampling valves, and in addition, due to the possibility of vaults or manholes being flooded with water, each transformer is fitted with a high-voltage and low-voltage pothead to which lead-covered entrance cables can be attached. A three-phase tap changer in the high-voltage winding is also used and controlled by a single hand-lever, operated outside of the tank. In addition, the high-voltage side of the transformer is fitted with a three-way disconnect and grounding switch such that the high-voltage line can be open or it can be connected to the transformer or solidly grounded for protection when necessary to do any work on the unit. This switch is operated outside of the tank and can be padlocked in each position. Inside the tank is an electrical interlock which automatically locks this switch when the transformer is energized.

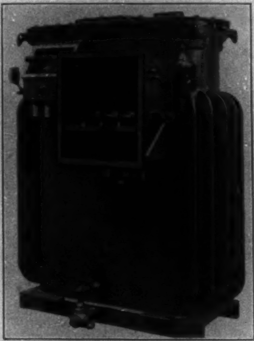

FIG. 10—THREE-PHASE NETWORK TRANSFORMER EQUIPPED WITH JUNCTION BOXES AND CABLE DISCONNECTING AND GROUNDING SWITCH IN PRIMARY JUNCTION BOX. JUNCTION BOXES OPEN. SWITCH IN OPERATING POSITION

An all-welded boiler-iron tubular tank is used with the high-voltage and low-voltage potheads made as an integral part of the tank. Each tank has a structural steel base to facilitate any moving of the transformer during installation. Lifting eyes are provided to handle the complete transformer. (Fig. 10.)

### CURRENT TRANSFORMERS WITH NICKEL-IRON CORES

The errors in a current transformer are due to the characteristics of the core material used. When this material has high losses and low permeabilities, the errors will be much larger than when the material has low losses and high permeabilities. Research work has resulted in the development of a new magnetic material called Hipernik which possesses exceptionally low losses and high permeabilities.

By the further development of a special magnetic circuit, which permits fuller use of the exceptional qualities of Hipernik, current transformers have been developed in which the errors are practically negligible, and far less than heretofore possible to make them using silicon steel. The application of these transformers is not confined to any particular class of secondary burdens, but may be used with any type of secondary burden within the rating of the transformer. Fig. 11 shows the appearance of one type of transformer developed.

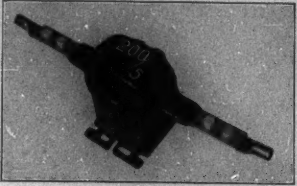

FIG. 11—PRECISION CURRENT TRANSFORMER USING HYPERNIK STEEL

Some current transformer units for use on 154,000-volt circuits were built during 1927. These are, so far as is known, the highest voltage instrument current transformers ever produced. Fig. 12 shows an interior view of one of these units.

The voltage limit in potential transformers was carried to a new figure in the manufacture of some units built for operating on a 220-kv. system in the East. Fig. 13 shows an external view of one of these transformers.

### A NEW TESTING OUTFIT FOR INSULATING OILS

The importance of keeping a careful check on the dielectric strength of oil used for insulation purposes is readily recognized. In most testing sets the variable high voltage necessary for testing oil is secured by switching a low voltage between taps on the primary side of the transformer. This method requires that the transformer be deenergized and then reenergized between taps. Such a method introduces distortions in the test voltage which lead to erroneous interpretation of the oil failure. A new method in which the transformer is energized at all times during an oil test has been devised and incorporated in a testing set shown in Fig. 14. In this set, the test voltage can be raised fairly smoothly without the introduction of transients;

hence, the voltage observed from the meter is a correct indication of the voltage at which the oil was tested.

The complete set is arranged in an aluminum case and can be carried in the same manner as a suitcase. It operates from an ordinary light socket at 110 volts, 60 cycles.

The a-c. high-voltage testing sets furnished during the year included complete equipment for several new laboratories. There were transformers, each rated 60 cycles, 300/600 kv-a., 250,000 to 1150/2300 volts and designed for chain connection to give 750,000 volts to ground. Individually, they are guaranteed for continuous operation and so far as known are the highest voltage units ever built for such service.

For use in making commercial tests on cables, there were built some 400-kv-a., 200,000-volt transformers, two of which were arranged in series to give 400,000 volts to ground.

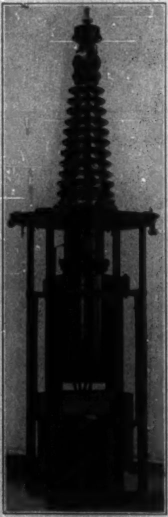

Fig. 12—Instrument Current Transformer for 155,000-Volt Circuit. 200/400 Amperes

One of the most complicated little testing transformers ever designed is one rated 60 cycles, 1.5 kv-a., 5010 to 110/220 volts, shown in Fig. 15. The high-voltage winding is so arranged that practically any voltage between 2 and 5010 may be obtained. Low reactance was specified and the measured impedance was 0.244 per cent.

### D-c. Kenotron Testing Sets

Two 400,000-volt sets, placed in service during the past year, gave the highest d-c. voltage so far used in commercial work. One of these installations is shown in Fig. 16.

There were several new equipments developed during the year, one, a 7500-volt set illustrated by Fig. 17, is unique in that it will be used for tests on 600-volt d-c. distribution feeders, a new application.

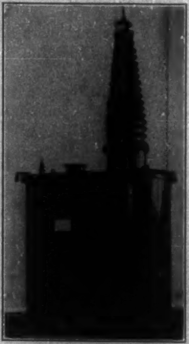

Fig. 13—Instrument Potential Transformer for 220,000-Volt Grounded Circuit

### Cable Entrance Junction Box Transformers

The development of higher-voltage cables, the desire of operators to avoid exposed connections, and especially the difficulty of making satisfactory end-bells, led to the adoption of transformers with cable entrances—the cable either terminating directly inside the transformer tank, or terminating in oil or compound-filled junction boxes which are connected to the transformer

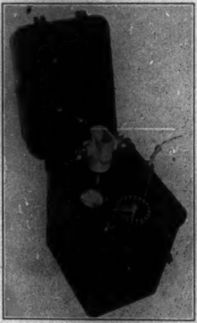

Fig. 14—Portable Testing Outfit for Checking the Quality of Transformer Oils

by means of bushings, both ends of which are immersed in oil.

Frequently, the necessity for routine testing of the cable requires means of readily disconnecting the cable from the transformer. To an increasing extent, disconnecting switches are fitted in the junction boxes with special testing bushings, so that the cable can be switched from the transformer to the testing connection or to the ground. Fig. 18 shows an installation of such transformers.

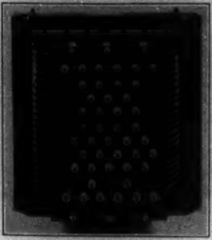

FIG. 15—LABORATORY VARIABLE RATIO TRANSFORMER, 1.5/5010 VOLTS

FIG. 16—INSTALLATION OF 400,000-VOLT D-C. CABLE TESTING SET

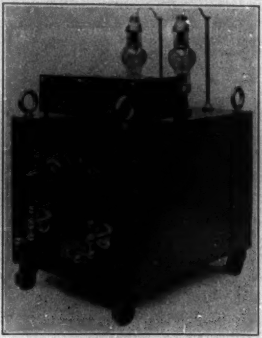

FIG. 17—D-C. CABLE TESTING SET. 7500 VOLTS END GROUNDED

A notable example of the adoption of this means of protection is found in the group of 20,000-kv-a., water-cooled transformers, furnished by one manufacturing company for the State Line Generating Company. These consist of 17 single-phase and 4 three-phase units, all of which receive current from the generator at 22,000 volts. The high-voltage ratings of seven of the single-phase units is 132,000 Y, the remaining ten being 66,000 Y, and three-phase units 33,000 Y. All these transformers are provided with cable-entrance bushings on the low-voltage side and all but the 132,000-volt units are equipped with cable-entrance bushings and self-contained disconnected switches on the high-voltage side. These transformers are also provided with load ratio control.

## SYNCHRONOUS MACHINES

The tendency toward larger machines in certain lines continued throughout the year 1927. This was true especially in connection with steam turbine generators, the sizes of which went up in erratic steps to 160,000 kw. for a single-shaft unit, and to 208,000 kw. for a three-shaft unit.

The trend in mechanical design was away from castings, so generally employed heretofore, since the first electrical machines were made, to the use of fabricated structures for practically all parts of the machine. These structures are made by welding together standard plates and standard structural shapes, such as beams, channels, and angles.

The trend in electrical design has been toward all possible reduction of losses and, consequently, attainments of higher efficiencies. The attack has been made, for the most part, on load losses, especially the losses in the mechanical parts due to stray fluxes.

Considerable thought has been given to the matter of improving the stability of machines by quick response excitation and superexcitation. A number of installations of such systems of excitation were in contemplation at the end of the year. Investigations and tests in the shops of various manufacturers were carried on.

## HYDRAULIC GENERATORS

There has been an increasing number of installations where automatic operation or distant control has been introduced.

Outdoor installation of hydraulic generators was often under consideration, but no important installation was made during the year.

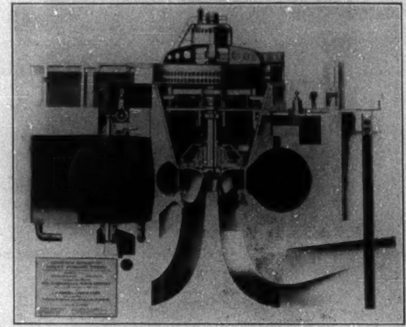

FIG. 19—SECTION THROUGH 40,000-KV-A. VERTICAL WATERWHEEL GENERATOR AND TURBINE

Great interest was shown during the year in the progress of the Conowingo Development on the Susquehanna River in the State of Maryland, under the direction of Stone & Webster, for the Philadelphia Electric Company, owners of the plant. The Annual Report of the Electrical Machinery Committee for 1926-27 gives considerable data on the generators, which are 40,000 kv-a., 81.8 rev. per min., 13,800-volt, 60-cycle machines. The present development consists of seven units; see Fig. 19, assembly in cross section of the combined wheel and generator. Six of these units were in operation June 1, 1928.

Both manufacturers introduced fabricated steel plate structures, but one of them used it to a greater extent. Practically the only parts of its machine that were made of castings are the upper bearing bracket and the hub of the rotor. Probably the most interesting and novel part of this generator is the rotor spider. Views of plate rim and arms are shown in Figs. 20 and 21.

At the close of the year one manufacturer reported a list of large hydraulic generators that had been put into operation, or had been made in its shops, or for which orders had been received during the year as follows:

2–45,000-kv-a., 50-cycle, 11,000-volt, 250-rev. per min. horizontal generators are the largest of their type yet undertaken;
4–29,000-kv-a., 12,000-volt, 60-cycle, 100-rev. per min. vertical generators, with direct-connected auxiliary generators which supply power for motor-generator exciter sets arranged for quick response excitation;
2–45,000-kv-a., 13,800-volt, 60-cycle, 400-rev. per min. vertical generators, with direct-connected exciter and pilot exciter;
2–45,000-kv-a., 13,200-volt, 60-cycle, 150-rev. per min. vertical generators;
2–22,500 kv-a., 60-cycle, 6600-volt, 120-rev. per min. vertical generators, with direct-connected exciters;
2–28,000-kv-a., 50-cycle, 11,000-volt, 300-rev. per min. vertical generators, with direct-connected exciters.

Another manufacturer reported installation and putting into service during the year two plants where the closed systems of ventilation were introduced. One of these is the low-head plant of the Louisville Gas & Electric Company on the Ohio River, which contains eight 12,550-kv-a. vertical 60-cycle generators running at 100 rev. per min., arranged for remote control. See Fig. 22. The other plant is that of the Washington Water Power Company, Lake Chelan, Wash., containing two 30,000-kv-a., 300 rev. per min., 60-cycle vertical units, the first one of which was put on the line during the fall.

Fig. 20—Assembled Rotor Run for 40,000 Kv-a. Conowingo Generator

The scheme of circulation of air is practically the same in the two plants. Eight water coolers are assembled at approximately equal intervals around the circumference, and arranged in pairs for circulating the air. In case of the smaller and lower-speed generator, all of the air passes into the pit underneath the generator and is driven out through the stator cores and windings by fans on the rotor, passing into the several sections of the stator frame and through the coolers, dropping down into conduits leading back into the pit. Every pair of coolers has an outside housing attached to the stator frame. In case of the larger and higher-speed generator, the outside housing is continuous, making a complete circle outside the stator frame, but the air into and out of every pair of coolers divides, a part of it passing upward and returning into the rotor via one of the four air pipes that connect into a common air chamber surrounding the top of the machine, and the rest of the air passes downward into conduits in the concrete foundation, and thence back into the rotor.

Fig. 21—Assembling Rotor Spider for Conowingo Generator

## STEAM TURBINE GENERATORS

Two or three European manufacturers of steam turbine units have designed or built 3000-rev. per min. generators with ratings as great as 37,500 or even 40,000 kv-a. The American manufacturers are more interested in 3600 rev. per min., or 60-cycle generators; 12,500 kv-a. generators of this speed were made during the year and 15,625 kv-a. was designed.

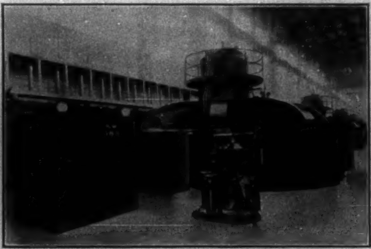

Fig. 22—Water-wheel Generators Showing Coolers Attached to Frame

The large 1800-rev. per min. generator mentioned in last year's report was installed and put in service during the year at Waukegan, Ill. It is rated 59,000 kv-a., 50,000 kw., 12,000 volts, and uses the closed system of ventilation with two external blowers and fin-type radiators. The operation of the generator has been satisfactory, especially in respect to quiet running and low temperature in both rotor and stator.

Skeleton types of stator frame, consisting of steel plate, welded or riveted, in place of castings, have been quite generally designed and built, especially for the largest generators. This construction results in machines that are not so limited by shipping facilities.

Among the more noteworthy large generators in process of manufacture is the cross-compound 188,000-kv-a. unit for the New York Edison Company, which consists of two 94,000-kv-a., 13,800-volt, 60-cycle, 1800-rev. per min. generators. These are the largest 1800-rev. per min. generators yet built. This unit is of special interest in that the separately driven fans for supplying the cooling air are the vertical type driven by 3600-rev. per min. induction motors, three fans in all, mounted between the generators. The air is discharged from the top of the generators into a common chamber from which the fans take it and pass it through the coolers back into the generators.

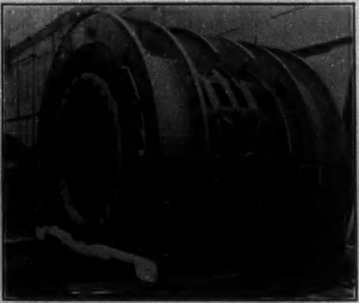

Fig. 23—Turbo Generator Stator with Ventilating Outer Skeleton Partly Assembled

Fig. 24—Hydraulic Bolt Puller for Tightening Through Bolts in Plate Type Turbo Rotor

This same company has extended the use of the skeleton stator frame to all large 1800-rev. per min. generators where shipping limitations require it. Fig. 23 shows a turbine generator with part of the superstructure installed.

This company has developed the plate rotor with forged shaft ends, and also has developed a hydraulic bolt puller for fastening together plates and shaft ends. A partial view of one of these rotors in the bolt-pulling machine is shown in Fig. 24. Two bolts can be pulled at the same time. The nuts are run on by hand after the plates are stretched, and this practise prevents thread friction and galling under the nuts. An improvement introduced during the year, in connection with built-up plate rotors, has been the making of the plates with holes in the center, in connection with which it has been found possible, by proper heat treatment, to raise the elastic limit on carbon plates from 23,000 to 55,000 lb.

During the year, the single-shaft generator units put into service by another manufacturer are as follows:

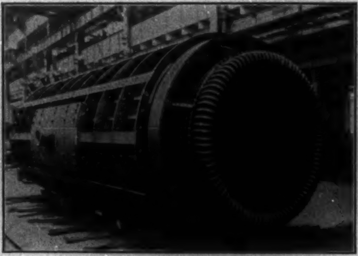

Fig. 25—Inner Skeleton Structural Frame for Turbo Generator

75,000-kv-a., 0.8-p. f., 1800-rev. per min. generator in the Edgar Station of the Boston Electric Illuminating Company, with direct-connected house service generator of 6250 kv-a., 0.8 p. f.;

A 55,000-kv-a., 0.9-p. f., 1800-rev. per min. generator in St. Louis. This generator has fans on the rotor and is at the present time the largest self-ventilated machine at 1800 rev. per min. that this company has built.

The first of this company's 22,000-volt generators was completed. It is 61,765-kv-a., 0.85-p. f., 1800-rev. per min. with direct-connected house service generator of 3571-kv-a., 0.7 p. f. It is to be installed in the Powertown Plant of the Superpower Company of Illinois.

The first of the two 100,000-kv-a., 1500-rev. per min., 50-cycle generators for the Southern California Edison was practically completed at the end of the year. The wound stator is shown in Fig. 25, while the outer stator frame is shown in Fig. 26.

Other single-shaft units in process of manufacture at the close of the year were a 66,667-kv-a., 0.9-p. f., 1800-rev. per min., 60-cycle generator, an 83,333-kv-a., 0.9-p. f., 1500-rev. per min., 25-cycle generator, and a 160,000-kv-a., unity power factor, 1500-rev. per min., 25-cycle generator. One of the features of the construction of the 160,000-kv-a. is the arranging of the stator winding as two entirely independent windings, each having capacity of 80,000 kv-a., connected through separate switches to adjacent bus sections. Two distinct advantages are to be obtained by this scheme; first, reduction in size of the individual switches; second, the elimination of bus reactors made possible by the transfer of power taking place through the coupling effect of the two separate windings.

In multiple-shaft units, it has nearly completed a 165,000-kv-a., consisting of three generators of practically the same rating for the American Gas & Electric Company, Philo Station. It also has begun work on a 208,000-kw. unit for the State Line Company consisting of one 89,412-kv-a. generator, and two 72,941-kv-a. generators, all at 1800 rev. per min. and wound for 22,000 volts.

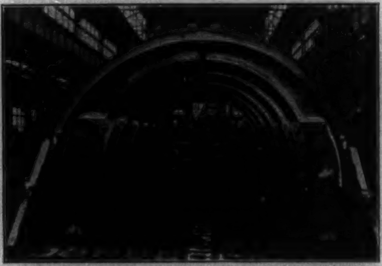

FIG. 26—OUTER SKELETON STRUCTURAL FRAME FOR TURBO GENERATOR IN FIG. 25

The advantages secured by the use of skeleton frame construction were set forth somewhat in detail in last year's report. They appertain chiefly to the matter of shipment. It has been found possible to design all three of the large generators in the 208,000-kw. triple-shaft unit State Line, with skeleton type frames, so that they may be wound at the factory and shipped complete, no outer frame or superstructure being required.

An advantage obtained by designing the stator frame with inner and outer parts like those shown in the photographs pertaining to the 100,000-kv-a., is the facility with which such machine may be made fit to contain some gas other than air in its ventilation system. There will be involved simply the removal of the outer frame and the substitution of a gas-tight structure of welded steel plates.

Additional tests in an atmosphere of hydrogen have been conducted during the year on the 6250-kv-a. generator mentioned in last year's report.

### MARINE TURBINE GENERATORS

During 1927 the two airplane carriers,—the *Lexington* and the *Saratoga*, were put into commission. They are the largest electrically-equipped ships afloat. Each has four 40,000-kv-a., 1755-rev. per min., 5000-volt generators. The motors, direct-connected to the propellers, are induction motors.

During the year the *SS. California*, plying from New York to San Francisco via the Panama Canal, was equipped, with a 48-cycle steam turbine generator, and synchronous motors. The ship is a large one of slightly more than 30,000-tons' displacement. The two turbine generators are rated 6600 kw. each, at 48 cycles. The reversible synchronous motors are 8500-hp. each, at nominal speed of 100 rev. per min. The speed of the ship is to be 18 knots with both turbines running.

### U. S. COAST GUARD CUTTERS

The economy of the centralized power plant has been adapted to the machinery now being installed in five U. S. Coast Guard Cutters. The machinery consists of a main turbine generator rated 2600 kw., a 3000-hp. synchronous propelling motor, condensing equipment, and electrified auxiliaries. In addition are two dual-drive units, each consisting of a high-speed turbine and gear, a direct-current generator, and a synchronous machine that is used either as a generator or a motor. Under the usual condition of operation the power for a-c. auxiliaries is supplied direct by the main generator and for the d-c. auxiliaries from the same source through the dual-drive unit. By this method of using the main turbine generator to furnish power for auxiliaries the total steam consumption has been materially reduced. During maneuvering or when the main unit is secured, all auxiliary power is supplied by the dual-drive unit, driven by its turbine.

### SYNCHRONOUS MOTORS

An increasing demand for synchronous motors was in evidence during the year. Undoubtedly it is safe to say that they are now being applied in certain cases where induction motors were formerly thought necessary. They are being introduced into steel mills where they were not formerly considered.

There was a decided demand during the year for "full voltage" or "across-the-line" starting. This has probably resulted from the fact that better starting torque efficiency has been introduced into synchronous motors by more skilful design, and to the fact that the systems on which they operate have become larger, relatively, to the individual motor.

For applications where the starting requirements are most severe such as driving large grinders in cement mills, as a rule, salient-pole machines have been furnished, many of them with double squirrel-cage starting windings, some with magnetic clutches, and some of the so-called "supersynchronous" type. The last-named consists of a motor with a stator that may revolve, and be brought up to synchronous speed with the rotor at rest, and with the clamps arranged to exert a braking effect on the stator to bring it to rest while the rotor comes up to full speed.

Another company has built during the year induction synchronous motors as large as 1500 hp. at 163 ⅓ rev. per min. Fig. 27 shows a 1500-hp. motor that has been in operation at the plant of the Atlas Cement Company. It starts like an induction motor with definite wound secondary and external resistance. After attaining rated speed, d-c. excitation at 50 to 60 volts is supplied from a small induction motor-driven set. Excitation required is, approximately, 500 amperes. It is to be noted that the windings in the rotor are much deeper than in an induction motor, since these windings serve as synchronous motor excitation windings.

### SYNCHRONOUS CONDENSERS

Quiet operation has been emphasized in connection with the placing of orders for many of the synchronous condensers built during the year. Two installations of 5000-kv-a., 750- or 900-rev. per min. condensers were made for the City of Los Angeles which were provided with the closed system of ventilation, containing radiator type of coolers mounted in the condenser foundation.

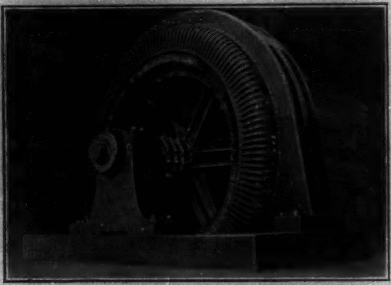

FIG. 27—1500-HP. 163⅓-REV. PER MIN. SYNCHRONOUS MOTOR FOR USE IN CEMENT MILL

It is interesting to note that during the year two of the 50,000-kv-a. synchronous condensers for the Southern California Edison Company were put into operation in two substations in Los Angeles. These large condensers also had the closed system of ventilation with air coolers underneath. It is probable that the purchaser of these condensers specified this method of cooling not so much on account of the reduction in noise as because they were machines of very large capacity at high speed, and also for the reason that he wished to equip the substations with carbon dioxide gas, or some other fire-extinguishing compound.

A 7500-kv-a., 900-rev. per min., 60-cycle condenser was installed in Malden, Mass., and a 10,000-kv-a., 900-rev. per min. in Springfield, Mass., both with closed systems of ventilation and air coolers. The reduction of noise to a minimum was the consideration in both cases.

Two synchronous condensers to be installed outdoors, and for hydrogen operation, were in process of manufacture during the year. The smaller of these, 10,000-kv-a., when operating in air, and guaranteed to be at least 12,500 kv-a. when operating in hydrogen, was completed during the year, but not tested at the close of the year, except to be filled with the most explosive mixture of hydrogen and oxygen. It exploded in the explosion-proof pit. This was done to make sure that no damage would be done to the structural parts of the machine in case of an explosion. Fig. 28 shows this condenser in the testing pit, with head removed, revealing the coolers, which are semicircular in shape and arranged two at each end.

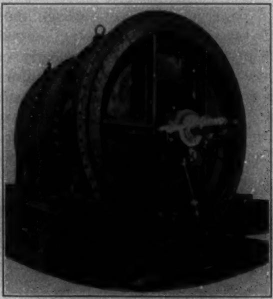

FIG. 28—HYDROGEN COOLED SYNCHRONOUS CONDENSER WITH END BELL REMOVED

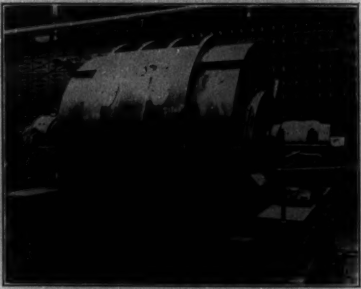

FIG. 29—7500-KV-A. SYNCHRONOUS CONDENSER SHOWING STRUCTURAL FRAME, END BELLS, AND BEDPLATE

Most companies are now building the 5000-, 7500-, and 10,000-kv-a., 60-cycle condensers at 900 rev. per min., instead of 720, thereby reducing weight, floor space required, and total losses.

Fig. 29 shows a 7500-kv-a. (condenser) with structural steel frame, end bells, base, sub-pedestals, etc.

Three 30,000-kv-a. condensers at 720 rev. per min. are now building for Philadelphia.

### FREQUENCY CONVERTERS

Nearly all frequency converter sets have synchronous machines at both ends. Probably the largest set of this type made during the year was a 29,400-kv-a., 25- to 60-cycle.

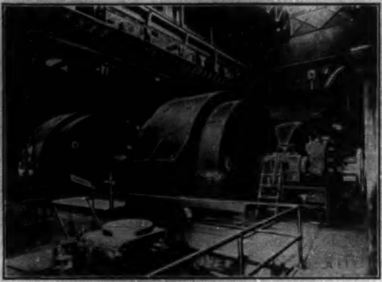

FIG. 30—21,400-KV-A., 25-CYCLE SINGLE-PHASE FREQUENCY CHANGER-SPRING MOUNTED

In cases where some flexibility in the voltage-tie between two systems is desirable, induction frequency converters may well be used. Such need may arise in the operation of synchronous converters, some of them from one of the systems, and some from the other, that feed direct current into common lines. Such a condition exists in New York City where large induction frequency converter sets have already been installed. Orders were placed during the year for two more 40,000-kw. sets.

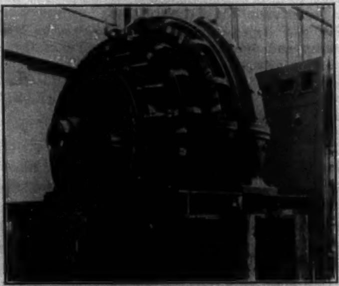

FIG. 31—4200-KW., 25-CYCLE SYNCHRONOUS CONVERTER

Fig. 30 shows a set rated 35,300 kv-a., three-phase, at the 60-cycle end, and 21,400 kv-a., single-phase, at the 25-cycle end, 13,600 volts. The 25-cycle end has a spring mounted stator frame. This set has been placed in operation in Philadelphia.

Orders have been placed for three 15,000-kw., 60- to 25-cycle sets for the same city. The rating of the 25-cycle, single-phase generator is to be 21,428 kv-a., 0.7 power factor. There have been furnished during the year two 60- to 25-cycle frequency changers for New Haven road, in which the 7140-kv-a., 25-cycle, single-phase generators had spring-mounted stators.

In certain cases, where the frequency converter serves as a tie between two systems, and is relatively small in comparison with the smaller of the two systems, Scherbius sets, or some equivalent that has flexibility in the frequency ratio, should be employed.

FIG. 32—4200-KW., 25-CYCLE SYNCHRONOUS CONVERTER. USING BENT SLAB FRAME AND ROLLER BEARINGS

Two sets of this type were being installed at the end of the year and one was put in service in April. These sets are to connect the 25- and 60-cycle systems of the Niagara Lockport and Ontario Power Company and are the largest sets of this kind yet built. The set is rated 25,000 kv-a., 20,000 kw. on the synchronous machine end and the induction motor which is rated 28,000 hp., 95 per cent leading power factor has the the largest rating of any induction motor in operation.

### SYNCHRONOUS CONVERTERS

Fig. 31 shows the commutator end of one of the two 4200-kw., 25-cycle lighting type converters for Edison three-wire service that were built on a certain order. The voltage range is 240 to 300, obtained by combination of transformer tap changing and field control. The base is structural steel.

Fig. 32 shows the collector end of a converter of the same rating, 4200 kw. The construction shown is typical of the present practise of one manufacturer. It utilizes a bent steel slab magnet frame, steel lugs welded on the sides to bolt the two halves together, and plate feet electrically welded to the lower half. The roller bearings are the first application made by this company of such bearings to a large converter. The pedestal supporting the bearing is made entirely of plates, cut and bent to shape, and electric welded.

There were built during the year, four twelve-phase, 4200-kw., 270-volt converters which are probably the largest twelve-phase converters in service in this country or abroad. The transformers were split into two sections, half being mounted on either side and connected to the brush-holder studs by copper bars, thus making a compact installation.

Also there were built four 5800-kw., 580-volt, 25-cycle converters for electrolytic work, the largest 25-cycle converters yet made for such service.

## INDUCTION MOTORS

The year 1927 resembled 1926 in the absence of spectacular or revolutionary achievements which specifically could be associated with the year in question. Satisfactory progress seems to depend more and more upon careful improvement of details in design, manufacture, and application. More complete and accurate knowledge of problems in lubrication, ventilation, balance and vibration, noise, and magnetic characteristics of materials, finally results in smaller, cheaper, and more satisfactory motors. Few really novel principles may be introduced into practical applications, but the principles already available are being more appropriately employed.

### QUIET MOTORS

Increased use of motors within office buildings, hotels, theaters, etc., has involved a demand for more rigorous standards of quiet operation. These standards are being met by more careful attention to several factors of design, especially of the magnetic circuit.

In addition to the improvements thus obtained in the reduction of magnetic noise, steps also have been taken with satisfactory results to reduce noise due to windage. In the case of some 2000-hp., 1800-rev. per min. blower motors for the Boston Edison Electric Light and Power Co., in which very quiet operation was desired, the result was secured by furnishing mufflers in the air outlet of the motors.

### TOTALLY ENCLOSED MOTORS

Lines of enclosed fan-cooled motors recently have been brought out which embody improved methods of circulating the air within the motor frame. These motors are much smaller and more economical than previous types, and so have extended the possibilities of applying motors in wet and dusty situations. The improvements in this type of motor represent a more exact knowledge of the process of removing and dissipating the unavoidable losses of the motors and the reduction of these losses wherever possible. (Fig. 33.)

FIG. 33—ENCLOSED VENTILATED BALL BEARING INDUCTION MOTOR.

### LOW STARTING CURRENT MOTORS

The increasing demand for high-impedance motors with adequate starting and pull-out torque has been met by careful studies of the principles introduced many years ago by Boucherot and others. It is only in recent years that a successful compromise between the inherent limitations of this principle and the current requirements of industrial applications has been reached. In 1927 the field thus covered has been extended still further, and several manufacturers now offer extensive lines of motors of this type. One manufacturer has brought out a new motor having movable steel bars in the rotor slots, which give high reactance at starting, but which are thrown out by centrifugal force as the motor accelerates, thus securing lower reactance in normal operation.

### FREQUENCY CONVERTERS

Frequency changers of the synchronous-synchronous type have been covered under the synchronous machines.

There are two other types of frequency changers, both of which use induction motors.

The synchronous-induction type uses a synchronous motor in concatenation with an induction motor, and provides a voltage tie as well as a frequency tie between the two systems. Several of these sets have been installed in Brooklyn and two more are in process of erection. The synchronous motor is 10 poles and the induction motor is 14 poles and rated 42,000 kv-a., 300 rev. per min., 13,800 volts stator and 2700 volts rotor. (See Fig. 35.)

FIG. 34—15,000-KW. SYNCHRONOUS INDUCTION FREQUENCY CHANGER, 25/60 CYCLES

Another of this type of 15,000 kv-a. has been installed by the Potomac Electric Light & Power Co. Tests show 94.5 per cent efficiency at full load. (See Fig. 34.)

FIG. 35—35,000-KW. SYNCHRONOUS INDUCTION FREQUENCY CHANGER DURING ASSEMBLY AS SEEN FROM THE INDUCTION MOTOR END

The adjustable ratio frequency changer uses an induction motor as the driving member and some means of speed control to adjust the speed to suit a change in frequency. Their advantages are that it is possible to use sets of smaller capacity than if they were of the synchronous-synchronous type. The amount of power and its direction can be controlled at the set by settings of the relays which control its action. It is much easier to synchronize due to the adjustable speed control on the induction motor. These advantages are offset by increased cost, a little less efficiency, and added complications to the control.

In several cases, however, they have been chosen as the correct type, as at New Haven and Long Island R. R. in railway service and in several points on the Niagara Power 25-cycle lines where other 60-cycle systems desire power. The 25-cycle system is not so constant as desired by the 60-cycle systems and the adjustable ratio set allows the 25-cycle circuit to vary and still have constant 60 cycles on the synchronous machine.

Four of these sets, rated 5000 kw., were installed last year and are used to convert power from polyphase to single phase for railway service in the New York district. One of the sets for tying together power systems is now running at the Niagara Lockport & Ontario Power Co. These sets are the largest of this type, each consisting of a 25,000-kv-a., 2000-kw., 60-cycle synchronous machine and a 28,000-hp., 25-cycle induction motor, both at 12,000 volts. They tie in the 25- and 60-cycle systems and run at 300 rev. per min. The synchronous motors have 24 poles and the induction motors 10 poles. These sets deliver a constant 60 cycles on the synchronous machine when the 25-cycle system varies between the limits of 2 per cent below and 1 per cent above normal. The auxiliary commutator machines are direct-connected to the main shaft, and are excited on their rotor winding through collector rings. (Fig. 36.)

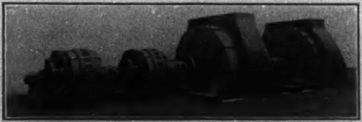

FIG. 36—SHOP VIEW OF 20,000-KW. ADJUSTABLE RATIO FREQUENCY CHANGER SET, 25/60 CYCLES

### HIGH-SPEED MOTORS

An increasing tendency to the use of high-speed motors for driving centrifugal pumps and air compressors was the practise in 1927. A relatively large proportion of these are being used for oil pipe line pumping, motors of as much as 250 hp. at 3600 rev. per min. being used for this purpose.

### SHIP PROPULSION

Although synchronous motors have been found preferable in some types of ship-propulsion equipment, the cases in which induction motors are still required are more numerous than was anticipated at the time the synchronous motor drive was introduced.

During the year, the second electrically-equipped self-unloading ore-carrier for the Great Lakes was completed and put in service, after satisfactory trial trips. This vessel had induction type main propulsion motors, and is the largest and most powerful ore-carrier on the Great Lakes. Induction motor drive is required on account of the exacting standards of flexibility in maneuvering imposed by the conditions of operation. Toward the end of the year the two airplane carriers *U. S. S. Saratoga* and *U. S. S. Lexington* were placed in commission and have been operated on their own power, although not as yet to full capacity. These induction-motor equipments were designed several years ago, and during the protracted period of ship construction have attracted attention on account of the great concentration of power involved.

Each of the 8 motors in each ship is rated at 22,500 hp. at 320 rev. per min., providing 180,000 for the ship. The size of these induction motors in hp. rating has been exceeded only recently by the induction motor on the adjustable ratio frequency changer sets mentioned above.

### STANDARDS

Agreements between the different manufacturers on standard shaft diameters and other dimensions have resulted in a recent general revision of general purpose induction motor designs. General advantage has been taken of this change to improve the design of bearings by the provision of larger oil wells and better methods of preventing oil leaks.

## D-C. MACHINES

The developments in d-c. machines have been in the increase of limits and reliability rather than in any startling discoveries. The commutation of extra large currents has been accomplished; speeds have been increased; and the mechanical design has been simplified.

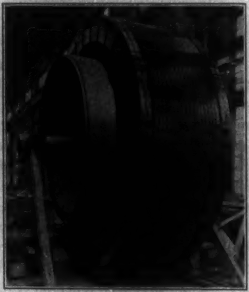

FIG. 37—ARMATURE FOR 7000-HP. REVERSING MOTOR SHOWING INVOLUTE EQUALIZER CONNECTIONS USED IN PLACE OF COMMUTATOR NECKS

*Commutation.* To improve commutation and decrease losses, especially in large units, involute equalizer connections were placed between the commutator and the armature winding in place of straight commutator necks. Fig. 37 shows these equalizers on a 7000-hp. reversing mill motor.

It has also been found that wave windings are successful in larger ratings than can be built with lap windings. This wave winding insures equal distribution of current in the armature circuit without the use of equalizers by virtue of the unusual mechanical distribution of the winding. Eleven 13,000-ampere synchronous booster converters and two 14,000-ampere field-control converters have been built with this winding and have shown improved commutating performance and reduced losses from the absence of equalizer currents.

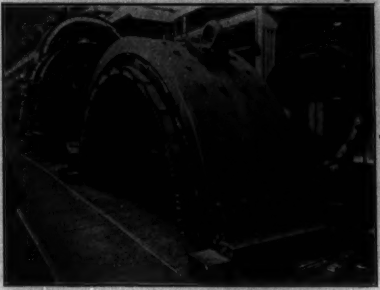

FIG. 38—A MAGNET FRAME MADE OF BENT SLABS WITH FLANGES FOR BOLTING HALVES TOGETHER WELDED ON

*High-Speed Motors.* Special requirements have led to the design of high-speed d-c. motors and results have been secured which would not have been thought possible even a few years ago. For example, during the last year, the Navy Department completed official tests on a special motor, the rating of which is 200 hp., 5000 rev. per min. This motor is used for driving a three-phase blower type compressor having a capacity of 3200 cu. ft. and a discharge pressure of 10 lb. New methods of design and construction had to be developed in order to build such a motor successfully. The peripheral speed of the armature is approximately 20,000 ft. per min. and the method of balancing was of the utmost importance. With the aid of a vibrometer, the rotor was balanced while rotating in its own bearings at the 5000 rev. per min. The bearings are flood-lubricated, oil being supplied by a separate motor-driven pump. The system of ventilation is simple and effective. The cooling air is actuated by the compressor and is drawn through the motor into the first phase of the compressor. The commutation was such that at the end of a 12-hr. duration test, the commutator surface did not show any sign of being burned or pitted.

*Welded Construction.* While welded frame motors have been on the market for a great many years, the use of this construction became much more general during 1927. In many cases, such parts as magnet frames, bases, spiders, and brush rigging are now being fabricated. Fig. 38 shows a magnet frame made of bent slabs to which flanges for bolting the halves together and supporting feet are electrically welded. Armature spiders have been built up of plate and bar material welded together on a steel hub for a large machine as shown in Fig. 39, and have been combined directly with the shaft for smaller machines, such as elevator motors shown in Fig. 40. The elevator motor shown in Fig. 40 is of further interest in that every part is of fabricated material without castings, except the rope sheave. The base is representative of such built-up parts as a substitute for castings. During 1927, the use of welded bases for all motors, generators, and motor-generator sets was extended rapidly.

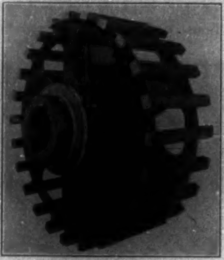

FIG. 39—ARMATURE SPIDER FABRICATED BY WELDING

FIG. 40—ELEVATOR MOTOR IN WHICH EVERY PART IS WELDED EXCEPT THE ROPE SHEAVE

*Adjustable-Speed Motors.* The principal development in adjustable-speed motors is to extend the speed range secured by field control beyond the conventional four-to-one range. Ranges of five-to-one and six-to-one have been secured. To secure successful operation at these higher-speed ranges requires very careful design and very accurate test adjustments. These higher-speed ranges have been particularly valuable in connection with application to reversing planers.

*Marine.* Motors for marine applications require special precautions against corrosion of the mechanical parts and against moisture in the windings. Although they must be installed in very cramped conditions, it is desirable to make major repairs without removing the motor from its position. If parts are not accessible, inspections will not be thorough. When failures occur, repairs must be made in the shortest possible time and often under extremely difficult conditions. Again, the application of motors aboard vessels may be taken as an example of the extreme length to which it is some times necessary to go in attaining accessibility. The case of propelling motors for submarines may be cited. The susceptibility of the lower field windings to failure has made it necessary to have some ready means of locating the defective coil and to arrange for its replacement without having to tear the ship apart. Test leads are brought out from the individual coils to a test terminal board and the whole magnet yoke is so arranged that it may be revolved in its housing and so make possible the repair or replacement of a defective field coil.

*Standardization.* For general purpose d-c. motors and generators, all manufacturing companies are now accepting such standardized dimensions as have been established by the National Electrical Manufacturers Association, with very considerable advantage, principally to the user, but also to the manufacturer. It is expected that during 1928 and 1929 still further progress will be made in this direction.

### OUTSTANDING INSTALLATIONS OR MACHINES IN PROCESS OF MANUFACTURE

*Marine.* Keeping pace with recent developments, Diesel electric drive is used to power *old type* Shipping Board vessels which, with changes in the hulls, will enable them to have greater speed, greater economy, and increased cargo capacity. Each of these ships will use a double armature d-c. motor, direct-connected to the propellor and developing 4000 s. hp. at 2 × 750 volts. The motors have been designed so that the most efficient propellor design and speed can be used, which in this case is 60 rev. per min. These will be the largest marine motors of this type in the world.

*Steel Mills.* The heaviest powered tandem hot-strip mill in the country is driven by 6 d-c. motors, each rated 2500 hp., 160/320 rev. per min., 600 volts. Power is supplied from 3 three-unit M. G. sets, each rated 3000 kw.

The heaviest powered hot-strip mill in the country requires 21,811 hp. for the main roll drive, which includes both a-c. and d-c. motors. The three a-c. motors on the roughing stands are mechanically interchangeable, although their ratings and speeds are different. The three intermediate stands are driven by three 2000-hp., 300/500-rev. per min. d-c. motors.

The four finishing stands are driven by four 3000-hp., 180/360-rev. per min. d-c. motors. The main roll d-c. motors are supplied from three 4000-kw. three-unit synchronous M. G. sets. Auxiliary motors and excitation for main drives are supplied from separate M. G. sets.

For replacing a steam engine on a reversing mill in the Chicago district, a 6500-hp. d-c. single-unit 0/60/140-rev. per min. motor will be used. This is being installed on the opposite side of the mill to reduce the shut-down period of the mill during the changeover. Welded construction is used in the bedplate for this motor and also for the flywheel M. G. set which supplies power to it.

A novel feature in a rod mill drive is the use of synchronous motor drive for all the stands except the finishing stand, which is direct current. Power is obtained from an M. G. set which at the same time drives some of the stands. The five synchronous motors have a capacity of 9600 hp. and the d-c. motor is rated 1200 hp.

### MERCURY ARC RECTIFIERS

At the close of 1927, there were in use in the United States and Canada 53 installations of mercury arc rectifiers having a total capacity of 44,450 kw., which may be compared with the 700,000 kw. installed in the entire world. As the first of the American rectifiers was purchased in 1923, fairly rapid progress in the adoption of the mercury arc rectifier for power conversion purposes is indicated. In the tabular appendix

TABLE I
MERCURY ARC RECTIFIERS IN RAILWAY INSTALLATIONS

| | No. of sets | Tanks per set | A-c. Cycles | A-c. Volts | D-c. voltage | Kw. per set | Total kw. | Control |

to this report, details of these installations, including frequency, voltage, and character of service of these 53 installations are given.

Reference to this appendix shows that most of the rectifier installations in this country have been made on railway systems, the few rectifier installations for Edison systems and industrial use amounting to less than 3500 kw. or 7 per cent.

Of the railway terminal electrification voltage class (1500-volt), 12,750 kw. capacity or 25 per cent has been installed, the remainder of the railway installations being of the 600-volt class and amounting to approximately 68 per cent. No installation of rectifiers for main line electrification purposes has yet been made.

In a few railway installations, dependence has been placed entirely upon rectifiers; but in most instances, rectifiers have been reinforced by converters previously installed in the same or adjacent substation.

Fig. 41—Five 1200-Kw. Mercury Arc Rectifiers at Bridgeport, Conn.

The outstanding installation during 1927 was that of the Connecticut Company at Bridgeport, Conn., which includes five 1200-kw., 600-volt units, without other converting capacity. In another substation at Stratford, the same company installed two units of the same size with complete automatic control. Fig. 41 shows these five 1200-kw. rectifiers at Bridgeport.

Another large installation of three entirely automatically-controlled 1000-kw. 650-volt units was made in the Hempstead Station to supply the Long Island Railroad.

* * * * *

Operating experience of various companies indicates that rectifiers lend themselves generally to any of the usual methods of control, the 1927 trend toward automatic control having been noteworthy.

Parallel operation of rectifiers and converters has not introduced serious difficulties, although a satisfactory method of the control of regulating characteristics of the rectifier has not been introduced.

Although current capacities and efficiencies which would warrant the use of a rectifier on the three-wire Edison system have not yet been attained, the obvious advantages of the rectifier, including its adaptability to various voltages and frequencies and the hopeful laboratory development of the manufacturers, give promise of rectifiers suitable for this service.

Limitation of current capacity has been the greatest retardant to the further extended use of the mercury arc rectifier in this country. In the development of regulating devices it seems desirable that some method other than the transformer ratio adjustment or the use of the induction regulator should be preferred.

Continuity of service is adversely affected to the greatest extent by internal short circuits within the tank. It is also adversely affected by impaired insulation within the tank and by the liberation of gas from the anode. Service restoration following interruptions which do not involve impairment of the vacuum is a simpler procedure than with synchronous apparatus, but when the vacuum is impaired the period of outages may be greater than with the flashover of a synchronous converter. Operating experience generally indicates the need of development of rectifiers along lines which will enable more rapid repairs when required within the tank. Elimination of the internal short circuit, which will dispose of this disadvantage, is hoped for, although it may be well to add that internal short circuits are usually not accompanied by impairment of the vacuum, and the rectifier may be put back into service immediately after an internal short circuit without any trouble.

Interference between rectifier and telephone circuits caused by the "ripple" in the rectified current depends largely upon the exposure between the circuits. Where the exposure cannot be reduced, band filters have been successfully used in the d-c. leads of the rectifier.

The advantages of the rectifier in voltages of 600 and above with respect to the converter for installation under limiting conditions of ventilation and permissible attendant noise are fully set forth in the manufacturers' statement which follows:

### MANUFACTURERS' STATEMENT

*Economic Advantages of Rectifiers over Synchronous Apparatus:*

Greatly reduced foundation.
Fractional weight.
Decreased transportation difficulties.
Simpler erection.
Simpler operation.
Lower operating costs.
Noiseless and vibrationless operation.
Adaptability to automatic and remote control.
Absence of synchronizing requirements.
Instantaneous starting and stopping.
Easier replacement of parts.
Increase of efficiency with voltage.
Higher efficiency over whole load range.
Independence of frequency.
Adaptability to high or low d-c. voltages.
High momentary overload capacity.
Possibility of cooling entirely by circulating water.

Some troubles experienced in the past with rectifiers were caused by corrosions, backfires, failure of the automatic vacuum valve, and telephone interferences. Today we have the necessary means at hand to overcome all these troubles. The effect of corrosion can be reduced to a negligible value by using long rubber hose connections at the cooling water intake, and a yearly overhauling and painting of the rectifier water chambers, or by using a forced draft cooling system insulated entirely from ground. In the matter of telephone interference there may be cases which would be difficult to correct and might involve expenditures of considerable magnitude. Backfires have been practically prevented by special screens inserted in the arc stream. An improved automatic vacuum valve is available and is entirely reliable. Telephone interferences wherever experienced have been very successfully eliminated by installing a special filter equipment.

The mercury seal has proved exceptionally reliable and has made possible tanks of 8 to 10 ft. in diameter. Also there has been developed by one manufacturer a unique seal consisting of a fused joint between porcelain and metal. Bushings may be removed and replaced without injury to the seal. A comprehensive system of automatically operating auxiliaries, including evacuating equipment, has been developed and a scheme of transformer connections giving the maximum utilization of transforming material without the balance coil gives promise of successful service.

The auxiliary equipment of one make of rectifiers has been considerably simplified. Anode and tank heaters and M. G. set for ignition have been abandoned. The excitation and ignition transformer, the choke coil, and the various insulation transformers are all mounted now in a common transformer tank. The auxiliaries consist of the following parts only: low- and high-stage vacuum pump; excitation and ignition; relay and transformer.

*European Developments.* In Europe the rectifier is in a great measure responsible for the steady increase of the d-c. voltages on railway systems. Already 800, 1200, and even 1500 volts are commonly used on urban, suburban, and interurban lines, with a few at 2400 and 3000 volts.

A typical example of a main railroad electrification is the 1500-volt Amsterdam-Rotterdam line of the Dutch Railways, which receives all the power from 20 Brown Boveri rectifier sets. There are several large industrial plants in Europe which depend entirely upon rectifiers as their power supply.

The most remarkable rectifier installation at the present time is the one of the Berlin Rapid Transit Company. Its system is the largest one exclusively supplied by rectifiers with a substation located at almost every passenger station.

This secures the advantage of having the power converting equipment just where the load demand is maximum, and of reducing the d-c. transmission lines and losses to a minimum. Moreover, the stray currents are greatly diminished, and consequently their destructive effect is also reduced. The interferences between d-c. lines, telephone and signal lines due to the pulsation in the rectified current are therefore practically eliminated. Altogether, the feeding of the "city" and "outer circle" railway lines require 34 substations with a total of 98 rectifier units, amounting to a total of installed capacity of 117,600 kw. The suburban lines branching out from the urban and outer circle lines are fed by 9 substations, each equipped with three or four units. Their total aggregate capacity is 36,000 kw. The primary supply for all these rectifier substations is 30,000-volt, three-phase, 50-cycle. The d-c. voltage is 800 volts.

The initial substation equipment is being supplied by Brown Boveri for this system and comprises for the initial development:

92 Rectifier cylinders, rated for a continuous output of 1200 kw. at 800 volts, with vacuum pumps and auxiliaries.

90 Rectifier transformers O. I. S. C.

90 Absorption reactance coils.

136-2000-ampere high-speed circuit breakers.

Other complete units are being supplied by other companies as follows:

10—Siemens Schuckert Works
10—Allgemein Elect. Co.
10—Bergmann Co.

The decision of the German Railways Company to use mercury arc rectifiers exclusively for the electrification of the important Rapid Transit Railways system of Berlin is of utmost importance for the future development of this type of converting apparatus, and shows clearly the confidence the engineers have in this equipment. The electrification of the Berlin Rapid Transit system will be no doubt the largest and most up-to-date rectifier installation in the world.

*Performance Standards.* Owing to the comparatively recent introduction of the mercury arc rectifier into this country the formulation of performance standards has not been undertaken to date. Definite procedure towards this end is, however, now under way. Performance guarantees of European practise will be studied and steps taken to put the matter of performance standards on a logical basis without hampering development.

# Transmission and Distribution

## ANNUAL REPORT OF THE COMMITTEE ON POWER TRANSMISSION AND DISTRIBUTION*

*To the Board of Directors:*

In addition to conducting its usual activities this committee has during the current year endeavored to establish a closer contact with those committees of other organizations whose interests lie in a large measure within the field with which it is concerned. It was felt that such cooperation would be mutually beneficial and would result in the presentation through the medium of the Institute publications of some material of general interest which would otherwise receive only limited circulation. It is believed that the present report has benefited very materially by this policy.

After considering some criticisms of the definitions contained in the "Wires and Cables" section of the A. I. E. E. Standards the committee deemed it advisable to have these definitions revised. A suggested revision has been prepared and placed in the hands of the Standards Committee.

The committee has been fortunate in securing several interesting and timely papers for presentation and publication by the Institute, some of which have not yet appeared. References to these papers will be noted under the appropriate headings in the following text.

### OVERHEAD TRANSMISSION LINES

*Lightning on Transmission Lines.* The protection of overhead transmission lines from interruptions due to lightning flashovers remains a problem of outstanding importance and in order to make more quickly available records of operating data on the protective value of ground wires, fused grading shields, and wood or combination steel and wood transmission line structures with regard to reducing lightning flashovers, a subcommittee undertook to collect as much information in this field as possible. A certain amount of information has been obtained and is presented herein, but more complete data are being sought and it is hoped to be able to present at an early date the inferences to be derived therefrom.

Table I gives data submitted by seven companies. Since no means avail to make direct comparisons of thunderstorm severity, it is obvious that while inferences may be made, conclusions cannot be drawn from these data.

Better performance resulting from adding a ground wire to an all-wood line seems clearly indicated from the comparison of 1926 and 1927 experience with that of 1925 of the data reported by companies No. 1 and No. 5. Similar improvements in reliability are indicated when ground wires have been added to steel tower lines.

On the other hand the data on the wood pole lines without ground wires, reported by companies No. 5 and No. 6, indicate in general less outages than the data on steel lines with ground wire, reported by others, indicating the apparent value of the wood as insulation in reducing flashovers.

Western companies report bird troubles as being more severe than those due to lightning, and wood construction very advantageous in this respect as shown by the data submitted by Company No. 6. However, there seems to be a crystallization of sentiment in the West in favor of steel towers with suitable bird guards, because of the very considerable trouble experienced with destructive fires due to leakage currents with wood construction, especially at certain seasons of the year.

Further light on the protective value of the ground wire is indicated by a comparison of the relative flashovers between 13 lines without ground wires totaling 412 mi. and four lines with ground wires totaling 229 mi.

Both groups are associated with the same systems, the lines being located in four different Middle West states.

There were in 1925, 36 interruptions for lines without ground wires, as against 2.2 interruptions for lines with ground wires, per 100 mi. of circuit.

Records for twelve consecutive years on a 110-kv. double-circuit line some 140 mi. long with single ground wire show an average of less than four interruptions per year per 100 mi. from lightning, and such interruptions constituted but one-third of the outages from all causes in that period. This line is subjected to as many as 70 to 80 electrical storms each year.

It may be noted that Company No. 8 had 36 and 28 breaker openings per 100 mi. in 1926 and 1927 respectively, although a ground wire was in service. Although this number seems large there may be satisfactory explanations which would become apparent if the somewhat insufficient data were more complete.

For lower voltage lines, 22 to 66 kv., there is an increasing tendency to try to improve designs of wood

pole lines with a view to reducing lightning troubles by the use of wood pins, arms and braces, and by increasing the amount of insulation inserted in the guy wires.

Company No. 1 reporting on the value of fused grading shields shows a fifty per cent reduction in outages on two circuits, on one tower line, so equipped compared with two circuits on a parallel tower line protected by ground wire only. It also states that this type of protection functioned correctly two out of every three times, *i. e.*, cleared the follow-up dynamic arc before the breakers opened and thus avoided dumping the load. The record as to the performance of the individual fuses was even better—77 per cent correct operation, *i. e.*, 77 per cent cleared properly and were not the cause of a line interruption.

Another company desirous of trying out this type of protection on 132-kv. circuits reports that it has not as yet been able to find a fuse for that voltage which, after testing, it felt was safe to install for this purpose.

The subcommittee has also secured a contribution to the report covering some of the more theoretical phases of this subject, and this constitutes the following material having to do with the theory of lightning and ground wires being herein presented not particularly as representative of the views of the committee as a whole, but rather as being of general interest and stimulative of further thought and study on the more theoretical aspects of this subject.

*Theory of Lightning and Ground Wires.* The results of the work of a number of investigators during the past year have altered to some extent the conceptions regarding the nature of the lightning stroke and the manner in which it affects transmission lines. The fundamentals of the "breaking drop" theory of the accumulation of the cloud charge, as proposed by G. C. Simpson, is generally accepted. According to this theory, the upward air currents in the front of the cloud, blowing past the condensed vapor in that region, break up the larger drops, as they form, and leave the divided parts with a positive charge. The passing air with finely divided spray carried off the corresponding negative charge to the upward and rearward portion of the cloud. Upon the recombination of the positive drops the potential is raised, due to the decrease in total surface; and likewise, in the negative part of the cloud the potential is raised as the charge is imparted to the vapor which condenses and forms into drops. According to this conception, the first part of the storm, and that with the heavy rain, is accompanied with the positively charged part of the cloud. The latter part of the storm, and the usually finer, drizzling rain, is accompanied with the negatively charged part of the cloud. Much of the accumulated charge of the cloud is carried to earth with the falling rain but the accumulation is, in general, more rapid than the dissipation by this means. The result is the familiar lightning flash between cloud and earth or between oppositely charged portions of cloud.

An electrical discharge between oppositely charged bodies starts, of course, when the stress at one of the electrodes reaches a state where ionization by collision begins. This state requires that potential gradient which gives free electrons a speed sufficient to knock off other electrons when they collide with neutral molecules. When an electron with this speed collides with a molecule but does not succeed in knocking off another electron, a considerable amount of heat is generated. If the stress reaches the breakdown potential of 30,000 volts per cm., the concentration of free electrons becomes so great, and the collisions with molecules become so frequent that the gas is heated to the point where thermal ionization begins. This forms the start of a streamer. Along such a streamer the gradient is low, which increases the stress at the ends. This further increases the concentration of ionization at the ends and promotes the progress of the streamer. Due to the difference between the speeds of negative electrons and positive ions, the speed of growth of the streamer toward the anode is much greater than that toward the cathode. This accounts for the difference between the growth of lightning strokes from negatively and positively charged clouds. However, in either case the speed is limited. It has been shown by various tests that with practical amounts of energy the maximum speed of growth of these streamers between electrodes of various shapes is of the order of one-tenth to one-fiftieth the speed of light. The completion of this arc establishes a conducting connection between the electrodes and an electrical current is free to pass, being governed by the impedance of the entire circuit involved.

In the discharge of a cloud to earth it is incorrect to consider the charge being released as concentrated in the first streamer. The streamer merely sets up the path, and as stated above, the growth is a relatively slow process. Considering the distances and speeds involved, it must take a time of at least 10 and probably 50 microseconds to accomplish this. After the path is established the charge is free to travel to earth as a traveling wave as fast as it can gather from the cloud. The progress of this is restricted, since the charge is distributed throughout a relatively non-conducting body. It is necessary for the path to branch out and collect the charge. Beyond this retarding effect, the rate at which the charge can pass to earth is determined by the potential of the cloud and the surge impedance of the lightning path. This surge impedance is a variable since it depends upon the diameter of the path and the distance above the earth. Although it is not quantitatively known it definitely limits the intensity of the lightning flash. When the lightning strikes a transmission line directly, the traveling wave from the lightning path divides, and propagates in two directions, with two-thirds voltage, in the same manner as when an ordinary line branches into two parts.

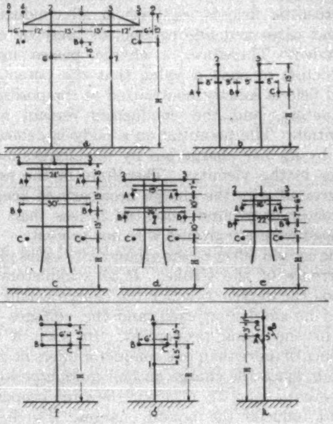

FIG. 1—TYPICAL ARRANGEMENT OF GROUND WIRES ON TRANSMISSION LINES

It is easily seen that this phenomenon limits the intensity of the surge, and many of them are probably quite weak. There is considerable reason to believe that, of the lightning surges experienced on transmission lines, a larger percentage is due to direct strokes than has generally been believed. In order for an induced surge to attain important magnitude, not only must the gradient be very intense, but the discharge must be extremely rapid. The gradient falls off rapidly from directly beneath the cloud outwards, and unless the discharge is extremely rapid the bound charge has time to distribute itself over the line.

It is now generally recognized that a great amount of protection is afforded by the use of ground wires on transmission lines. Much of the disrepute into which ground wires fell was due to poor mechanical installation and the use of non-weather-resisting material, which did not provide a life comparable to that of the rest of the line. In the installation of ground wires the same degree of weather resistance and the same quality of installation should be used as in the rest of the line so that the ground wires do not fail previous to the line conductors.

Ground wires are valuable in protecting the line both from induced and direct strokes. The manner in which the ground wire protects against induced strokes is as follows: Due to the slow rate at which the cloud electrostatic field is established, all conductors, both ground wires and line conductors, may be considered grounded. Therefore, a charge passes up on the conductors of such a value that the potential of the cloud field is exactly neutralized at the positions of the conductors, and the conductors remain at ground potential. The potential on a body is determined not only by its own charge but by the charges on all other bodies in the vicinity. Therefore, in the presence of the ground wire the charge necessary to keep the line conductor at ground potential is less than would be required were the ground wire not present.

The second effect of the ground wire takes place at the occurrence of the stroke. If all conductors were insulated the degree to which the charge would be bound would be similar on each, and the voltages would all rise in the same proportion. In such a case, the presence of more than one conductor offers no protection to each, since the charge on one conductor would raise the potentials on the others in the same proportion that it had reduced the bound charges. Furthermore, if the discharge of the cloud were instantaneous the ground wire would offer no protection, since the bound charges would then have no time to readjust themselves, and upon the disappearance of the cloud field the charges would be those which would raise the potentials of the conductors to the potentials of their positions in the cloud field before the stroke, but of opposite polarity. However, in the actual case the ground wire is grounded, and there is a certain time lag in the disappearance of the cloud field. It has been assumed that this time lag is sufficient to permit the necessary readjustment of charges on the ground wire to keep it at ground potential in the absence of the cloud field and the presence of the charge on the line conductor, the latter not being able to get away on account of the higher insulation and the rapidity of the field collapse. During the past season, klydonographs have been connected to ground wires at a number of locations, and the highest potentials recorded near a tower were of the order of 20,000 volts, which verifies the validity of the above assumption. It is obvious that, in order to remain at ground potential in the presence of the charge on the line conductor, the new charge on the ground wire must be of opposite polarity. This charge of opposite sign reduces, rather than raises, the potential on the line conductor due to its own charge. A simple way of stating the effect of ground wires in connection with induced strokes is, that it decreases the capacity of the line conductor to ground before the stroke and increases this capacity after the stroke.

Quantitatively, ground wires reduce the potentials induced on lines by lightning by from 25 to 75 per cent, depending upon the number and arrangement of the ground wires. The number of ground wires to use is of course an economic problem to be considered in relation to the amount of protection desired.

The most efficient arrangement of the ground wires is that which gives the greatest geometrical mean radius of the ground wire system and the least geometrical mean distance of this system from the conductors being protected. Table II gives the protection afforded by various numbers of ground wires on lines of various standard voltages.

The amount of protection afforded by ground wires against direct strokes is not so easily determined. However, since the ground wires are, or should be, located above the line conductors they are much more likely to receive the stroke of lightning than the conductors themselves. In view of the limitation of the intensity of the lightning stroke, as discussed above, it is easily seen that the less severe strokes might hit the ground wire and still not induce sufficient voltage on the line conductor to cause a flashover.

The protection against flashover afforded by the use of ground wires is much greater than the percentage reduction in voltages. If the number of lightning surges of any given potential is plotted against the voltages, the resulting curve resembles a rectangular hyperbola. From this it is seen that of those lightning strokes, both direct and induced, which cause flashover, those that are not more than twice the flashover voltage of the insulators are much more numerous than those which are many times that value. Therefore, if each surge is reduced to one-half its voltage, the number of flashovers is reduced by a much larger factor. Operating experience of the past few years seems to indicate that on the higher voltage lines flashovers are practically eliminated by ground wires which give a 50 per cent reduction.

*Topography in Relation to Lightning Flashovers.* An investigation of the flashovers which have occurred on the Cahokia–Crystal City transmission line, which was put in service May 11, 1925, indicated a close relationship between the topography of the surrounding territory and the flashovers on the line. This relationship was demonstrated by plotting on a topographical map the location of all the flashovers whose positions

H* = Height of lowest conductor.

have been reported since the line was put in service.

This line follows the low lands on the Illinois side of the Mississippi River to a point opposite Crystal City where it crosses to the high bluffs on the Missouri side. On the western side there are no high hills, except those near Crystal City. On the eastern side, steep bluffs parallel the line almost for its full length at a distance of from one to three miles. The prevailing path of the storms in this part of the country is from the directions between southwest and northwest.

The flashovers have occurred in groups with four to five miles having excessive flashovers and adjacent sections of similar length having but few. At the southern end, clouds pass over the high hills on the west side of the river and discharge to or near the line, causing a large number of flashovers. Farther north the clouds coming from the southwest do not pass over any high hills, retain their charge, pass over the bottom lands and discharge to the bluffs on the eastern side. At the time of discharge the cloud probably extends back over the line and the sudden release of the charge induced on the line by the passage of the cloud over it causes flashover. The nearer the line to the bluffs the greater the number of flashovers.

A number of flashovers along two miles of line, some three or four miles south of Cahokia, cannot, however, be accounted for on the above basis.

From this study, it appears that short sections of ground wire placed over the portions of the line most subject to flashovers should be almost as effective from the standpoint of protection as a ground wire over the entire length. Eight miles of ground wire divided into four sections would include those parts of the line upon which 70 per cent of the flashovers have occurred. The line is a double circuit one, 31 mi. in length. Two miles of ground wire have been installed over the Missouri bluffs and the other six miles will be installed as outlined above. It may well be that partial protection of this type will offer a maximum of insurance for a minimum of investment.

*Symposium on Surge Voltage Investigations.* Attention is called to the symposium on surge voltage investigations which is on the program of this convention and is being presented under the auspices of this committee (see p. 1111). Some of the papers in this group are in the nature of reports of progress of investigations which are not as yet completed and further reports will be awaited with the same interest with which the present papers will undoubtedly be received.

One paper of this symposium, entitled *Surge Voltage Investigation on the 132-Kv. Transmission Lines of the American Gas & Electric Co.*, presents the preliminary results of an extensive klydonograph layout which was planned and placed in operation during 1927 in connection with studies of the Subcommittee on Lightning. The investigation was made possible through the cooperation of the General Electric Co., the Westinghouse Electric & Manufacturing Co., and the American Gas & Electric Co.

The data secured during 1927 require further study and are too incomplete at present for many definite and final conclusions to be drawn. Switching surges were recorded up to 5.2 times normal to ground, checking quite closely previous data on this phase of the problem: All switching surges were either highly damped or unidirectional with small magnitude. These surges do not appear to be at all troublesome to line or apparatus, at least in the line investigated. Lightning voltage surges were recorded up to 4.8 times normal and in one case where the line tripped over 19 times normal was found. Of the surges recorded 57 per cent were positive, 18 per cent were negative, and 25 per cent oscillatory.

Lightning arrester discharges were found as high as 2620 amperes in the neutral leg of a four leg oxide film arrester on a 132-kv. system. Another case of 1260 amperes was observed. Both currents were negative initially, the latter being highly damped.

Voltages on the protective ground wire were observed as high as 20,000 volts in one case, and many voltages were recorded in the order of 2000 to 3000 volts.

The work, so far, indicates that surges of lightning origin having an initially high value, do not spread far on the line before rapid attenuation reduces them very materially. The waves are highly attenuated in the first five miles or so of travel.

Voltage surges due to switching were found to travel the entire length of the 73-mi. line with little apparent attenuation. There was a noticeable reflection of the voltage at the open end of the line which died out in a few miles of return travel.

On these particular lines it was found that the voltage surge on deenergizing the line was about double that which was found on energizing the line. Switching on these lines was done on the 132-kv. circuit, and not on the low side of the step-up transformers, a condition which is thought to have influenced the results. Further data are being obtained on this feature of line switching.

The field investigation is being continued in 1928 and it is expected that after the data for 1928 have been collected and assimilated a fairly complete report can be presented.

*Insulation of Transmission Lines and Connected Apparatus.* The tendency in power transmission has been to increase the insulation of some portions of the system, particularly the line, to a point at which it is fairly immune from flashover due to lightning. This tends to place a greater stress on the other apparatus and therefore requires a corresponding increase in its insulation.

The papers on *Relation between Transmission Line and Transformer Insulation*, by W. W. Lewis, (see p. 1111) and *Rationalization of Transmission-System Insulation Strength*, by Philip Sporn, (see p. 1132) which were presented at the New Haven Regional Meeting, point out the anomalous features of this situation and suggest concrete steps to be taken toward its rectification.

*Horizontal Spacing of Transmission Line Conductors.* While the horizontal spacing of conductors in a transmission line is ordinarily determined by the clearance necessary at the tower to permit the swinging inward of the insulator strings, there are, nevertheless, cases where this spacing is determined to avoid danger of contact of the conductors out in the span. Among such cases are the occasional lines with six horizontally spaced conductors on one tower (as in the case of the Davis Bridge Line of the New England Power Company) and long spans; also some wood pole lines where the poles do not carry a ground wire.

A paper by Mr. P. H. Thomas (see p. 1323), covering this subject in detail and proposing an empirical formula for the determination of the necessary spacing as depending upon the danger of contact out in the span, has been secured and is being presented at this convention.

*Transmission Line Conductor Vibration.* Investigations have been carried on through the year on the vibration of transmission line conductors of various materials in service. These records obtained in the field have been supplemented by experimental work at the Carnegie Institute of Technology in Pittsburgh.

The general results of these records and investigations are covered in a paper by Theodore Varney, (A. I. E. E. Quarterly TRANS., 1928, Part 3, p. 799), read at the St. Louis Regional Convention on March 9, 1928.

These investigations confirm the fact that resonant vibrations are due to wind of rather low velocity. The effects of these vibrations are more marked when the conductor or cable consists of a strong material giving a high elastic limit, as would be expected.

It appears that practically all wires or stranded cables suspended in the air are in a constant state of vibration. It is only, however, when the wind velocity is uniform throughout the span and bears certain definite relations to the elastic characteristics of the span that resonant vibration of considerable amplitude is set up.

Resonant vibration of considerable amplitude has been observed and recorded in many cases. In comparatively few of these cases has damage to the conductor or cable resulted. It is to safeguard such cases, however, that the investigation has been carried on and comparatively simple methods for overcoming these difficulties have now been suggested.

In view of the complexity of the problem and the consequent difficulty of prophesying in advance whether or not trouble may arise, it appears probable that some one of the several comparatively simple safeguards which have been developed should be considered in the design of any new transmission line of importance.

It is believed to be a simple and sound principle to reinforce a transmission conductor at its point of support, particularly if the spans are long, the weather conditions severe, and the line important.

*Movements of Overhead Line Conductors during Short Circuits.* A paper by W. S. Peterson and H. J. McCracken, Jr., covering a considerable amount of experimental data on the movements of overhead line conductors due to electromagnetic forces under short circuit conditions was presented at the Pacific Coast Convention in August (A. I. E. E. Quarterly TRANS., Vol. 48, No. 1, Jan. 1929). In overhead lines where heavy short circuit currents are encountered, this is a feature of design which cannot be neglected, and it is hoped that the paper mentioned, together with other available information, will make possible a more rational treatment of this problem.

### UNDERGROUND CABLES

*General Review.* The outstanding feature of underground transmission during the year is the placing in service in the summer of 1927 of 18 mi. of 132-kv. lines in Chicago and New York. These installations were described before the Institute at the Chicago Regional Meeting in November 1927. There have been no electrical failures on these installations, and the only troubles have been minor oil leaks in joints and other appurtenances and a few leaks in cable sheaths. In all cases of leaks the repair work was deferred until the line could be taken out of service without inconvenience to the operating company.

No marked developments in the design of underground cable for general use have taken place during the year. Impregnated paper insulation is very generally employed and wood pulp paper is rapidly replacing manila paper. The advantages due to the superiority of the mechanical properties of manila rope paper over wood pulp paper have very largely been overcome by reason of improvements in the production methods with wood pulp paper. On the other hand, the latter has a higher dielectric strength than the manila paper which has thus far been used and research investigations have shown it to have as high temperature limitations. Sector shape conductors are being very largely used in high voltage three-conductor cable. Shielded type three-conductor cable is being marketed by a number of manufacturers for the higher operating voltages and some manufacturers of single-conductor cable for extra high voltage three-phase operation are recommending the use of the shielded type of construction for such cable.

All of the available evidence indicates that on the whole there has been a distinct improvement in the quality of high voltage cable during the past few years. Statistics on more than 5,000,000 ft. of such cable purchased under rigid specifications by a group of central station companies show that only 3.22 per cent of the cable submitted during 1927 was below the standards prescribed by the specifications,—the lowest of continually decreasing percentages during the past five years. There has been a steady increase in dielectric strength of cable during the past few years. Dielectric losses and power factor are at about a minimum,—the average power factor for cable with a wide range of voltage ratings and sizes being about 0.6 per cent at room temperature and operating voltage.

Another outstanding feature has been the marked decrease in the effect of bending on the dielectric strength of paper-insulated lead-covered cables. For the past two or more years cable could be subjected to a very severe bending manipulation without any appreciable effect on the dielectric strength.

Existing specifications provide certain maximum allowable operating temperatures for impregnated-paper-insulated cables depending upon the rated voltages. Neither these specifications nor the standards of the A. I. E. E. specify a method of determining the maximum temperature in the cable during operation. In order to make a start on clearing up this situation the subcommittee on impregnated-paper-insulated cable research has made arrangements with the Massachusetts Institute of Technology for studies on the thermal resistivity of impregnated paper insulation, including the devising of a standard method of measuring the resistivity which will be acceptable to the manufacturers and users.

*Cooperative Activities.* A number of the central station companies that purchase large quantities of underground cable annually, cooperate in the inspection and testing of new cable, in the analysis of a large amount of inspection and test data thus made available, and in a certain amount of experimental research work. These statistical analyses are the basis of the above statements in reference to quality improvement.

Among the research studies which have been made, one on the relative dielectric strength of single-conductor versus three-conductor cable indicated that single-conductor cable has a dielectric strength which, if expressed as the average voltage gradient which will cause failure in 10 hr., is about 60 per cent greater than that of three-conductor belted type cable, the advantage over shielded three-conductor cable being about half that amount.

Manufacturers of cable, however, are in good agreement that the advantage in dielectric strength of single-conductor cable as compared to three-conductor belted cable for these conditions is only about 30 per cent, with a corresponding reduction to possibly 15 per cent for shielded three-conductor cable. Further investigation of the data will probably serve to reconcile the discrepancies between these figures.

Another rather extensive investigation has established the relationship between life and voltage for modern cable, namely, that the life varies inversely with approximately the sixth power of the voltage in the case of single-conductor cable and approximately the seventh power of the voltage in the case of three-conductor cable within the range of the test.

*Effectiveness of Specifications and Cable Performance.*

The effectiveness of specifications and the accompanying inspection and tests in guaranteeing satisfactory service of cable are often questioned and few data exist from which definite conclusions may be drawn. Obviously the answer to this question can be found only by following the history of inspected cable after it goes into service. The importance of this question and the still greater importance to the operating engineer of thoroughly reliable records of cable performance have been recognized and all of the important data in connection with all failures of cable in service on a number of the larger systems are now being systematically collected. It is believed that these studies will yield some very important results but they have not yet been continued long enough to justify conclusions. However, it has already been found that a very considerable percentage of the sections of cable which failed in service without external cause had some abnormal feature of more or less significance in the original inspection record.

*Quality Rating.* It is generally recognized that all items of inspection and test are not of equal value, and that no one characteristic determines the quality of a given piece of cable. On the other hand it is probably true that no two engineers will agree as to just which characteristics do determine cable quality. Nevertheless it is appreciated that a method of weighing characteristics, assigning grades on a scale of test performance for each characteristic and thereby obtaining a single figure of merit for a given lot of cable, would furnish an engineer with a useful means of evaluating that cable. Such a procedure of quality-rating has been set up and is now being applied in the cooperative work referred to above. Such a procedure, even though strictly empirical, will, if it proves to coordinate with service records, be of great value to the industry.

*Losses in Armored Single-Conductor Cables.* The calculation of potential drop and energy loss in single-conductor steel armored cables used for three-phase circuits is not susceptible of accurate predetermination with the information now available.

In 1909, J. B. Whitehead and H. W. Fisher (TRANS. A. I. E. E., Vol. 28, p. 737, and TRANS. A. I. E. E., Vol. 28, p. 747 respectively) published some experimental data on this subject supplemented by theoretical discussions. The Whitehead formulas are revised in the light of further discussions in Wm. A. Del Mar's *Electric Cables*, 1924, p. 142.

Since that date the subject of drop in *unarmored* single-conductor cables has been very fully discussed in series of monographs in the *Journal* of the Institution of Electrical Engineers (London 1926 and 1927) and the theoretical principles evoked seemed to warrant the more careful study of the case of armored cables.

The main features that differentiate the latter from the former case are the difficulty of calculating the magnetic flux in the steel wires in view of the indefiniteness and variability of the air-gaps between them and the variability of the magnetic properties of armor wire.

The variety of iron armored single-conductor cables tested and the data obtained have not been sufficient to permit establishing a generally applicable calculating procedure for circulating currents and losses. While the data available cover sufficiently well for practical use the loss calculations for the few designs considered, iron armored cables of radically different design would probably require additional empirical data to be derived from tests, as a basis for the calculations. If the proper additional tests were made for a few other types of armor designs, a more general calculating procedure could probably be established.

A paper[1] is under preparation reviewing the knowledge at hand, and reporting the results of recent tests and analysis as a further step of progress toward a more general understanding of the problem.

In general the use of copper armor in place of steel will greatly reduce the losses in a submarine cable. In many cases either copper or iron armor is mechanically feasible; and the question as to which should be used in a given project will then be decided on an economic basis. The paper will include an analysis of the economic factors involved.

*Alternating-Current Electrolysis of Lead Cable Sheaths.* The use of single-conductor cables in separate ducts for three-phase circuits of high voltage has led to the adoption of various methods for the reduction of induced currents in the sheaths. These schemes entail a-c. potentials from the sheaths to ground of varying magnitudes and the question of whether electrolytic corrosion of the cable sheaths is likely to result from this practise is of considerable importance.

The phenomena involved in the alternating current electrolysis of lead are complicated by the chemical nature of the electrolyte. However, B. McCullum and G. H. Ahlborn state that in general under ordinary soil conditions electrolytic corrosion appears to be practically negligible when the period of the cycle is not greater than about five min. For the details of their findings reference should be made to Tech. Paper 72, Bureau of Standards 1916.

J. L. R. Hayden (TRANS. A. I. E. E., Vol. XXVI, p. 201) comes to the conclusion that electrolysis on alternating current rarely exceeds one-half of one per cent of the electrolytic action of the corresponding direct current.

Hayden also found that the superposition on an alternating current of 1.5 per cent of its value in direct current protected the lead against corrosion, the effect of course occurring when the cable was negative to the ground. E. R. Shepard (TRANS. *Am. Electro Chem. Soc.* 31, 239-51, 1921) in a paper entitled "Electrolytic Corrosion of Lead by Continuous and Periodic Currents," finds that with direct current the coefficient of corrosion in both tap water and earth decreases with an increase in current density, reaching a minimum of about 50 per cent for current densities of five milliamperes per sq. cm. The theoretical maximum of 100 per cent is found for low current densities of the order of 0.5 milliamperes per sq. cm. and less.

---

[1] By O. R. Schurig, H. P. Kuehni, and F. H. Buller.

If, however, certain salts are present in the electrolyte so that the lead ions may react to produce an insoluble compound a comparatively large amount of corrosion may occur even with alternating current. Further investigations of this subject are under way and will doubtless add much valuable information to our present supply, which is none too complete.

It may also be appropriate to mention here that some trouble has been experienced with lead sheath corrosion due to the formation of a red lead oxide. The 1915 report of the N. E. L. A. Committee on Underground Construction indicated that reversals in polarity of the sheath of long duration would be effective in producing corrosion of this type. More recent results indicate that such corrosion may occur quite independently of electrolytic action, but whether or not d-c. or a-c. electrolysis may be an important factor in accelerating such corrosion is somewhat in doubt. This subject was discussed at a special meeting during the April Regional Meeting, which was held in Baltimore, and as a result of investigations now under way more detailed knowledge will probably soon be available.

*Summary.* While, as stated, no startling progress has been made during the year, attention is called to the significance of the many cooperative activities now under way, a few of which have been mentioned above. The greater attention being given to underground cable by operating companies as evidenced by this cooperative work, and the constantly increasing research work being done by the operating companies individually and by the manufacturers, all justify expecting continued improvement in high-tension cable.

*Papers Presented during Year.* Several papers have been presented during the year which are of interest to engineers concerned with the design and operation of underground cables. Among them may be listed the following:

*Joints in High Voltage Multiple Conductor Cable*, by Thos. F. Peterson, TRANS. A. I. E. E., Vol. 46, 1927, p. 963.

*The Influence of Residual Air and Moisture in Impregnated Paper Insulation*, by J. B. Whitehead and F. Hamburger, Jr., JOURNAL A. I. E. E., Sept. 1927, p. 939.

*High Voltage Measurements on Cables and Insulators*, by C. L. Kasson, TRANS. A. I. E. E., Vol. 46, 1927, p. 635.

*Electric Strengths of Solid and Liquid Dielectrics*, by Wm. A. Del Mar, W. F. Davidson, and R. H. Marvin, TRANS. A. I. E. E., Vol. 46, 1927, p. 1049.

*Influence of Internal Vacua and Ionization on the Life of Paper Insulated High Tension Cables*, by Alexander Smouroff and Leo Mashkileison, A. I. E. E. Quarterly TRANS., July 1928, p. 731.

*132,000-Volt Single Conductor Lead Covered Cable*, by P. Torchio, L. Emanueli, W. S. Clark, A. H. Kehoe, C. H. Shaw, J. B. Noe, and D. W. Roper, A. I. E. E. QUARTERLY TRANS., Vol. 47, No. 1, January 1928, p. 186.

### POWER LIMITS OF SYSTEMS

Further progress is reported in the development of methods for predetermining power limits of systems and of criteria for system stability. From this standpoint, important progress has also been made in synchronous machine theory.

A number of papers bearing on the problem of power transmission has been presented during the year. Three of these presented at the Winter Convention (bibliography references 1, 2, and 3) have added materially to the underlying theory as well as outlining methods for predetermining with practical accuracy those characteristics of synchronous machines which are of importance from the standpoint of stability. A paper on power limits with several machines connected to the system was presented at the Pacific Coast Convention (reference 4). A mechanical method of calculating power limits is described in a paper presented at Baltimore (reference 5).

Last year's report indicated the extent to which high speed or quick response excitation had been adopted as a means of preserving synchronism in a system during short circuits. The installations made to date are the Farmersville substation of the Southern California Edison Company, the Gatineau Falls Development of the International Paper Company, and the Conowingo Development of the Susquehanna Power Company. The experience obtained to date with these installations has been insufficient to draw any definite conclusions regarding their effectiveness in maintaining stability. Without such operating experience, the committee has no further statement to make except to repeat the opinion generally held, that there is a number of cases where quick response excitation may be advantageous. It is not a panacea for system troubles. The question of its application, of the quickness of response, and of the "ceiling" exciter voltage, should be determined by a study of the particular conditions of a given case. Certain limitations common to all systems, such as saturation effects and rotative speeds, have been covered in a recent article (reference 10). Although there may be cases where conditions would not warrant a special excitation system to obtain rapid voltage build-up, there are cases, nevertheless, which justify very special means to secure not only extraordinary quick response, but also a high value of exciter voltage. For illustration, such equipments have been purchased by the Philadelphia Electric Company as part of five 30,000-kv-a. condensers which are being installed at the Plymouth Meeting and the Westmoreland substations of Philadelphia Electric Company. No operating data, of course, are as yet available. Installations of this character have been described before the Institute and in the technical press (references 7 to 15, inclusive).

Further progress is reported in factory tests of power transmission, using voltage regulating devices, substantiating previous tests demonstrating the possibility of stable operation under a condition of dynamic or artificial stability, that is, at values of power considerably above the limit with fixed excitation (references 13 and 14). It is thus a promising development as regards increasing the maximum output of synchronous machines. It is expected that even if it is not necessary at the present time to transmit regularly values of power above the steady-state limit, there may be occasions when certain branches of a system may be momentarily loaded beyond the steady-state limit, due to switching operation, sudden load shifts, etc., and the devices referred to should prove beneficial under such conditions. Data have also been obtained indicating that these devices, in conjunction with exciters of appropriate characteristics, materially improve the transient stability of a transmission system, that is, the ability of a system to carry through short circuits, and that they assist in helping to steady down a system which has been set into violent oscillation as the result of a severe short circuit.

There is an urgent need for further field data. These data should take two forms:

a. Further tests on systems for which calculations have been made, as a check on such calculations.

b. Data secured during transients encountered in normal operation, by means of special recording devices, such as the automatic oscillograph and the high speed recorder. Preferably these data also should be obtained on systems for which calculations have been made.

Some work has already been done along the latter line, and has been reported to the Institute (reference 16). In addition, there is a need for further data on the total impedance in the path of short circuit currents flowing from conductor to neutral at the values of current ordinarily encountered in such short circuits. A method for obtaining these data, together with a discussion of the effect of ground resistance upon the stability problem, has recently been published (reference 17).

It is felt that in the problem of maintaining synchronism between all machines connected to a system during short circuits, very considerable benefit will be obtained by reducing as far as possible the magnitude and duration of the disturbance caused by a short circuit. It is not generally practicable to reduce the short circuit current by the introduction of series impedance in the path of load currents as this decreases the power limits directly. Since, however, most short circuits occur from line to neutral, considerable benefit may be expected from making use of means which limit the value of line to neutral short circuit current without increasing the impedance of the system to normal load current.

For illustration the following means are available:

1. In the case of an a-c. low voltage network by feeding the network from a number of small step-down stations, thereby limiting the current caused by a short circuit on the distribution system.

2. Grounding only part of the transformer banks at any one point.

3. The introduction of impedance devices in the neutral connection. Other means may be desirable in special cases.

In the belief that the trend in the future will be in the direction of reducing fault currents without increasing the impedance of the system to load currents, the committee therefore recommends that in the case of new systems or in the case of extensions to or changes in existing systems, consideration be given to means of reducing such fault currents.

For papers and articles reference should be made to the Bibliography (2) covering this subject.

### ACKNOWLEDGMENT

The material in this report has been obtained from a multiplicity of sources and includes contributions made through the courtesy of committees of other organizations as well as those of subcommittees and individual members of this committee. Without making a detailed acknowledgment, the chairman wishes to take this opportunity of expressing to the contributors as a group the appreciation of this committee as well as his own personal thanks for the generous manner in which they have all given so unstintedly of their time and information.

PHILIP TORCHIO, *Chairman.*

## Discussion

**D. W. Roper:** Mention is made in the report of the underground 132-kv. cable installations in New York and Chicago. I think the report would properly be supplemented by a statement of the service record of that cable. There are approximately 36 mi. of cable in New York and 18 mi. of cable in Chicago. The latter installation has been in service nearly 13 months and the New York installation nearly 11 months. The total service record amounts to nearly the equivalent of 50 mi. of cable for one year and during this time there have been no electrical failures, a record which I believe is unequaled by any recent performance of any underground cable from the time when the first installation of a higher-voltage cable was installed in this or any other country.

The paper mentions also some trouble with red oxide of lead on underground cables in certain locations. There was a meeting at Baltimore to discuss the subject. The results of that meeting and subsequent experiments did not get reported to the Chairman in time to be included in this report and I thought they might be interesting.

The clue was given by a peculiar condition in Chicago, where a concrete conduit was cast in place. The conduit was so enclosed that air could not reach it readily. This conduit was connected to another conduit made of pre-cast sections and so located that water might drain from the first conduit into the pre-cast conduit. Corrosion was found on cables in both conduits, but mostly in the lower conduit.

In the disucussion at Baltimore it was brought out by cement experts that cement requires carbon dioxide for setting as well as moisture.

In the case of the monolithic conduit, there was abundant moisture, but apparently a deficiency of carbon dioxide. Evidently the carbon dioxide absorbed by the water seeping into the concrete structure from the surrounding earth was all given up to the outer portion of the concrete. The water, continuing its course through the concrete to the interior of the ducts, picked up the alkaline hydrates from the uncured concrete and then ran down through the conduit and into the other conduit. The alkaline hydrates attacked the lead sheaths principally in the pre-cured ducts, which are only slightly inclined. This was confirmed by analyses of the water taken from the ducts which show hydroxides of lead and calcium.

The action of these hydrates can be stopped temporarily by the application of carbon dioxide gas to the ducts or allow it to bubble up through the water in the ducts; but the relief obtained in this manner is only temporary. Analyses taken a few days after the application of the gas again show a dangerous amount of the alkaline hydroxides. The trouble has continued for over 15 months after the installation of the monlithic conduit, and a solution for the trouble has not yet been found.

In this case, where the corrosion was due to chemical action, the products of corrosion are generally from a yellow to a deep red color, while in mild cases of electrolysis extending over several years, the corrosion products range from a white to a light yellow in color.

The conclusion is that when ducts are cast in place at least a month should elapse to give the concrete time to set before cables are installed.

**Harold Michener:** I should like to say a little about vibration. We of the Southern California Edison Company think the subject of conductor vibration is very important and probably should be emphasized more than it is in this report. I think we have published more about our troubles due to conductor vibration than any other company. We feel that we have solved the problem, and that with the use of these vibration dampers we can hold any conductor so that it will not vibrate appreciably.

I think this should be considered very carefully in connection with the ground wires as well as in connection with the conductors. I would recommend particularly that those who are putting up ground wires in suspension clamps expecting them to prevent breaking of the ground wires at the points of support should keep very close watch of those points of support. We feel that when there is vibration the thing to do is to stop the vibration rather than try to put some arrangement at the points of contact that will ease off the deteriorating effect that the vibration has even though flexibility and easy entrance curvatures undoubtedly are of some benefit.

**M. T. Crawford:** Since submitting data to the committee from which the figures in Table I, Company 5, were compiled, I have secured additional data covering simultaneous years operation of another company's 110-kv. wood-pole transmission line running through the same territory. This line was built with a ground wire throughout, whereas the line shown in the committee report was without the ground wire. It is interesting to note that over a three-year period this line averaged 0.88 breaker openings per hundred miles per year, which is very close to the average of the values shown for the wood-pole lines without ground wires for Company 5 through the same period.

These lines are located in the Puget Sound region where lightning is comparatively infrequent, but with over a thousand miles of line and in a three-year period the results should be fairly indicative of the value of the ground wire and do not seem to show that the ground wire is economically justified under conditions obtained in this locality. As a result of this analysis, the Puget Sound Power & Light Company is now building additional 110-kv. wood-pole transmission lines about one hundred miles in length and no ground wire is being installed.

**Philip Torchio:** Numerous data have been collected in recent years regarding lightning disturbances on transmission lines and the preponderance of the evidence available indicates quite clearly that a great deal of protection may be expected from the use of ground wires. In some cases, such as the one mentioned by Mr. Crawford, the ground wire has not appeared to give the anticipated benefits and it is to be hoped that future records of operation and studies of the local conditions will disclose the reason for these variations. There are so many variables involved in studies of this kind that it is only by the analysis of records which cover a long period of time and which have been most carefully correlated with the local conditions that helpful deductions can be made. Fortunately, we now have the klydonograph which is of invaluable aid in carrying on these investigations.

# Protective Devices

## ANNUAL REPORT OF COMMITTEE ON PROTECTIVE DEVICES*

*To the Board of Directors:*

The principal work of the Committee this year has been—, *first*, arranging for and the actual preparation of papers for presentation at meetings of the Institute, of which there have been one or more presented at practically every meeting of the Institute, and *second*,—the work of standardization, the result of which work is reported below.

The work of the Committee has been carried on by subcommittees, each under the direction of its own chairman, and after the first organization meeting at New York in September further meetings have been held by the subcommittees individually. The subjects covered and the chairmen in charge of the subcommittees are as follows:

Current Limiting Reactors, A. H. Sweetnam, Edison Elec. Illum. Co., Boston, Mass.

Communication Circuit Protection, H. W. Drake, Western Union Tel. Co., New York, N. Y.

Industrial Control Equipment and Service Protection, R. C. Muir, General Electric Co., Schenectady, N. Y.

Lightning Arresters, J. A. Johnson, Niagara Falls Power Co., Niagara Falls, N. Y.

Circuit Breakers, Switches, and Fuses, J. M. Oliver, Georgia Power Co., Atlanta, Ga.

Reactors, W. H. Millan, Union Elec. Light & Power Co., St. Louis, Mo.

### SUBCOMMITTEE ON INDUSTRIAL CONTROL EQUIPMENT AND SERVICE PROTECTION

The subcommittee has prepared a revision of the A. I. E. E. Industrial Control Standards. This revision is in process and not finished sufficiently to be presented at this time.

### SUBCOMMITTEE ON COMMUNICATION CIRCUIT PROTECTION

The subcommittee has arranged for several papers and is giving active study to the question of standardization.

Reports of other subcommittees attached.

## Proposed Standards for Lightning Arresters

## No. 28

*Prepared by Subcommittee on Lightning Arresters*

Corrected to April 12, 1928

### SCOPE

The standards in this section shall apply to all types of lightning arresters embraced within the classifications given in paragraphs 28-100 and 28-101.

### SERVICE CONDITIONS

28-1 *Usual Service Conditions.*—Apparatus conforming with these standards shall possess its specified characteristics and be capable of successful operation:

a. When and where the ambient temperature does not exceed 40 deg. cent. for air.

b. Where the altitude does not exceed 1000 meters (3300 ft.).*

28-2 *Unusual Service Conditions.*—The use of apparatus under conditions other than noted under (28-1) shall be considered as special. Other conditions which may require special consideration are:

a. Temporary overvoltage (such as may occur due to apparatus or line regulation, and/or generator over-speed, following sudden loss of load).

b. Sustained overvoltage (such as may result from accidental arcing grounds on one-phase of a circuit of which the neutral either is not earthed or is earthed through a considerable resistance).

c. Sustained overvoltage (such as may appear on non-earthed circuits by induction from unbalanced parallel higher voltage circuits in close proximity, or by contact with circuits of higher voltage).

d. Sustained overvoltage caused by removal of neutral connection to earth in combination with a grounded conductor (such as may occur on part of a system when it is disconnected from, or located at a great distance from, the part of the system having the neutral earthed).

e. Exposure to damaging fumes, vapors, or dusts.

f. Exposure to salt air.

g. Operation in damp places or climate.

h. Exposure to steam.

i. Exposure to excessive oil vapor (which may, by condensation and accumulation, change the characteristics of spark-gaps, or be ignited by a spark and produce a conducting flame).

---

**COMMITTEE ON PROTECTIVE DEVICES:**

F. L. Hunt, Chairman,
H. R. Summerhayes, Vice-Chairman,
E. A. Hester, Secretary,
R. E. Argersinger,
Raymond Bailey,
A. C. Cummins,
H. W. Drake,
W. S. Edsall,
L. E. Frost,
James S. Hagan,
Herman Halperin,
F. C. Hanker,
J. Allen Johnson,
R. L. Kingsland,
M. G. Lloyd,
K. B. McEachron,
W. H. Millan,
R. C. Muir,
J. M. Oliver,
A. H. Schirmer,
H. P. Sleeper,
A. H. Sweetnam,
F. D. Wyatt.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

*The limitations of temperature and altitude are adopted for the purpose of uniformity with other standards. Manufacturers consider as standard an altitude up to 1214 meters (4000 ft.).

j. Exposure to excessive dust.
k. Exposure to explosive gases or dusts.
l. Exposure to abnormal vibration or shocks.

Where such conditions exist, it is recommended that they be brought to the manufacturer's attention.

### DEFINITIONS

28-50 *Lightning.*—Lightning is an electrical discharge* occurring in the atmosphere from cloud to cloud, between cloud and earth or within a cloud.

28-51 *Lightning Surge*†.—A lightning surge is a transient electrical disturbance in an electric circuit caused by lightning.

28-52 *Test Surge.*—A test surge is an electrical impulse of specified characteristics produced for the purpose of laboratory tests.

28-53 *Lightning Arrester.*—A lightning arrester is a device providing a path for electric current between an electric circuit and earth through which, upon occurrence of a lightning surge, current will be conducted in sufficient amount to reduce the over potential of the circuit caused by the surge, and thereafter will cease to be so conducted.

28-54 *Discharge Current.*—The discharge current of a lightning arrester is the surge current which flows through the arrester to earth upon the application to its terminals of a lightning or test surge.

28-55 *Follow Current.*—When surge current passes through a lightning arrester there is formed a conducting path through which generated current‡ may also flow. The generated current which follows the surge current through the arrester in this manner is called the "follow current."

28-56 *Ground (Noun and Verb).*—A conducting connection, often accidental, between an electrical circuit and earth, or any other conducting or partly conducting structure or material.

The term "ground" is used loosely, There may be no connection with the real ground or earth. For example, when a porcelain insulator is punctured and a conducting path is formed between the supported line wire and the supporting metallic pin it is customary to say the line is "grounded" to the pin in spite of the fact that the pin may be thoroughly insulated from earth by a dry wooden pole and crossarm. An overhead ground wire is said to be "grounded" to a steel tower although the tower may not be earthed.

28-57 *Earth (Noun and Verb).*—An intentional electrical connection or contact with the earth.

Unlike "ground," the word "earth" when used in this sense is an unequivocal term having but the one meaning. Earths are usually made by driving one or more metallic pipes or rods into the earth; by burying metal plates or other conducting material in the earth with suitable connections thereto or by connecting with metallic materials (such as water pipes) already buried in the earth. The resistance of an "earth" depends in general upon the extent of contact with the soil, the degree of moisture present, the nature of the soil and its soluble content.

28-58 *Series-Gap.*—A spark-gap connected in series with a lightning arrester, to keep the circuit through the arrester open under normal conditions and to close the circuit for the lightning discharge by sparking.

28-59 *A Horn-Gap.*—Is a spark-gap equipped with metal horns to assist in interrupting follow current. Such a gap is sometimes used as a series-gap with a lightning arrester.

28-60 *A Protected Series-Gap.*—Is a series-gap protected from rain and other precipitation by a roof or cover.

28-61 *Characteristic Element.*—The characteristic element of a lightning arrester is that part of the arrester whose function it is to control the discharge current, and suppress the follow current.

28-62 *Cathode Ray Oscillograph.*—An oscillograph in which the moving element consists of a pencil of cathode rays. Such a moving element has no inertia and hence can be made to record accurately transients of extremely short duration.

28-63 *Microsecond.*—A time interval of one-millionth ($10^{-6}$) second.

### CLASSIFICATION

28-100 *Classification According to Use.*—Lightning arresters may be classified according to the uses for which they are designed and intended, as follows:

a. As to kind of circuit to be protected; as power or communication type.

b. As to location; as line or station type.

c. As to weather protection; as indoor or outdoor type.

---

*When such a discharge between cloud and earth terminates on a transmission line, apparatus, or other objects with which we are concerned, it is called a "direct stroke" of lightning.

Although direct strokes may be destructive, they usually strike electrical systems only in the transmission circuits, where, in the present state of the art, it is not economic to protect completely against them. Lightning arresters are not, in general, designed to protect against direct strokes.

†In relation to the circuit as a whole a lightning surge usually takes the form of a traveling wave or transient in space. In relation to any given point of the circuit, however, such a surge manifests itself as a transient in time. A lightning surge manifesting itself as such a time transient at a point in a circuit may be caused by:

1. A direct stroke of lightning at or near the point.
2. A traveling wave caused by a direct stroke elsewhere on the circuit.
3. Release of bound induced charge at the point (as by nearby discharge of cloud).
4. A traveling wave resulting from release of bound charge elsewhere on the circuit.

‡In these standards the current, voltage, and frequency that are supplied to the circuit by the source of power are called respectively, generated current, generated voltage, and generated frequency.

d. As to nature of generated circuit current; as d-c. or a-c. type.

e, As to system connection; as for earthed or non-earthed neutral.

28-101 *Classification as to Control of Follow Current.*—There are two general types:

a. Valve Type: A valve type arrester is one whose characteristic element has a high effective resistance at normal line potential, which resistance decreases with increasing potential and returns to its original value as the applied potential returns to normal. These characteristics result, in general, in suppression of follow current.

b. Follow Current Type: A follow current type arrester is one which permits follow current to flow. Some arresters of this type effect the interruption of the follow current by means of the operation of some current interrupting device, and others by means of the cyclic nature of the generated voltage in combination with some property of the characteristic element.

### Rating

28-150 *Rating Defined.*—A rating of a machine, apparatus, or device is an arbitrary designation of an operating limit. Lightning arresters are given voltage ratings only and are rated in terms of generated r. m. s. circuit voltage.

28-151 *System Voltage Rating.*—The system voltage rating of a lightning arrester is the rated r. m. s. system voltage upon which the arrester is intended to be used. This rating will usually determine the general insulation requirements of the arrester.

28-152 *Maximum Voltage Rating.*—The maximum voltage rating of a lightning arrester is the maximum operating r. m. s. voltage to which the arrester should be subjected.[*] This rating determines the breakdown voltage of the series-gap and the protective characteristics of the arrester.

### Characteristics and Performance

28-160 *Characteristics Enumerated.*—The suitability of a lightning arrester for its purpose depends upon the degree in which it possesses three characteristics or properties, *viz.*:

1. Protective ability of which its "protective characteristic" is a measure.
2. Ability to perform its operating cycle.
3. Permanence, involving both its ability to retain its protective ability and to repeat its operating cycle. The measure of this latter ability involves both the frequency and number of such repetitions.

28-161 *Protective Characteristic.*—The protective ability of a lightning arrester under given conditions[†] depends upon the voltages to which it limits the surge and the times during which it permits such voltages to be maintained. Since protective ability is a function of both voltage and time, it cannot well be expressed by a single quantitative value, but is better indicated by a curve with time and surge voltage as coordinates. Such a curve obtained under controlled test conditions is the "protective characteristic"[‡] of the arrester under those conditions, and when obtained under the standard test conditions specified under 28-201 shall be called the "Standard Surge Protective Characteristic" of the arrester.

28-162 *Operating Cycle.*[**]—The operating cycle of a lightning arrester embraces the following actions:

1. At the start of the cycle the circuit through the arrester is open thus permitting no current to flow. (In arresters without series-gaps a very small current may flow.)
2. Upon the occurrence of a lightning surge or other transient potential exceeding a certain voltage the series-gap breaks down and/or the effective resistance of the characteristic element decreases, permitting surge current to pass through the arrester.
3. Surge current continues to flow so long as sufficient surge potential persists and may be followed by generated current—depending upon the type of arrester.
4. Upon cessation of the surge potential, or its reduction to some lower value, surge current

---

[*] Since a lightning arrester is intended as a protective device against transient overvoltage, its breakdown voltage is necessarily lower than that of the apparatus it is designed to protect. Its voltage rating, therefore, must have special consideration. Increasing the generated voltage at the terminals of an arrester above its maximum rating reduces its factor of safety and may result in its destruction at the time of discharge. On the other hand, choosing an arrester of a rating above the usual maximum voltage of the circuit to meet abnormally high generated voltage on the system reduces the effectiveness of the arrester as a protective device.

[†] The ability of a lightning arrester in service to protect apparatus against lightning surges depends in part upon certain conditions external to the arrester itself. Among such conditions are:

a. The characteristics of the incoming surge.

b. The surge impedance of the circuit over which the surge arrives.

c. The number and surge impedance of circuit branches starting at or near the point of connection of the arrester.

d. The length and impedance to surge current of connection from circuit to arrester and from arrester to earth.

e. The distance along all circuit branches between point of connection of lightning arrester and the apparatus to be protected.

f. The characteristics of the apparatus to be protected.

[‡] The relative effects of the magnitude and the time of application of voltage in causing breakdown of insulation are not as yet definitely known. A "protective characteristic" of a lightning arrester is a measure of its ability to protect against the surge by which it was obtained, but cannot be evaluated in absolute terms until insulation characteristics are better known than at present.

[**] The successful performance by a lightning arrester of its operating cycle is in no degree an indication of its protective ability which depends upon other characteristics and conditions.

ceases to flow and at some time thereafter the follow current—if present—is interrupted, thereby restoring the arrester to a condition of open circuit.

At the completion of its operating cycle an arrester should be in condition to repeat the cycle immediately, although it shall not be assumed that the cycle may be thus repeated indefinitely.

The performance of its operating cycle should not appreciably alter the protective characteristic of the arrester.

### TESTS

28-200 The following tests shall apply to all arresters except those with large electrostatic capacity used without series gaps.

### TESTS FOR PROTECTIVE CHARACTERISTICS

28-201 *Standard Surge Protective Characteristic.*—Tests to determine the standard surge protective characteristic of a lightning arrester shall be made by the use of a test surge, the voltage of which shall be unidirectional and shall rise at the rate stated in 28-202 until the arrester begins to discharge, after which the discharge current through the arrester shall rise at the rate of 100 amperes per microsecond to a crest value of 1000 amperes and thereafter decrease to 500 amperes in not less than 10 microseconds.

28-202 *Rate of Voltage Rise of Standard Test Surge.*—The rate of voltage rise of the standard test surge prior to beginning of arrester discharge shall be as follows:

a. For arresters or arrester sections of low voltage rating up to 11 kv.-100 kv. per microsecond.

b. For arresters or arrester sections of ratings higher than 11 kv. the rate of rise of voltage of the standard test surge shall be increased proportionately, *i. e.*, 200 kv. per microsecond for a 22 kv. arrester, etc.

28-203 *Parts of Arresters to be Used for Protective Characteristic Tests.*—For determining the protective characteristics of low-voltage arresters up to 11 kv. system voltage rating, the entire arrester shall be used (single pole). For arresters of higher voltage ratings tests may be made on suitable sections of the arrester whose combined voltage ratings do not exceed 11 kv., with series-gap set for proportionate sparking voltage, and the results extrapolated.†

28-204 *Other Protective Characteristics.*—Tests for protective characteristics with test surges other than standard may be made, but in every such case the exact characteristics of the test surge employed, including the rate of voltage rise prior to beginning of arrester discharge, rate of current rise thereafter, crest value of current, and duration or rate of decay of current, shall be stated or shown by suitable cathode ray oscillograms.

28-205 *Use of Cathode Ray Oscillograph.*—Protective characteristics of lightning arresters shall be determined by the use of a cathode ray oscillograph.

### TESTS FOR PERFORMANCE OF OPERATING CYCLE

28-210 *Parts of Arrester to be Used.*—Tests for the performance of its operating cycle may be made upon a single pole of the arrester and in the case of valve type arresters of sectional construction may be made upon suitable low voltage sections at proportionate generated voltages and with proportionate series-gaps.

28-211 *Characteristics of Test Circuit.*—The arrester shall be connected across a circuit of voltage equal to the maximum rated voltage of the arrester or arrester section under test and of such power capacity and impedance that the generated voltage across the arrester shall not be decreased more than five per cent below rated voltage for a period of more than one-half cycle of generated current at the crest of the follow current. A non-inductive load, which in the case of higher voltage arresters may be a transformer with loaded secondary, shall be connected across the arrester terminals, so adjusted that generated power current of the order of five to ten amperes shall be flowing past the arrester during the test.

28-212 *Initiation of Discharge.*—Discharge shall be initiated by a test surge so timed as to start follow current as early as possible in a half cycle of generated voltage. If no follow current flows the surge should strike at the crest of the generated voltage wave.

28-213 *Oscillographic Record.*—Voltage and current relations during the period of follow current flow shall be determined by the use of an oscillograph, the electromagnetic type being suitable for this purpose.

28-214 *Standard Operating Duty.*—The standard operating duty of a lightning arrester shall be ten operating cycles at intervals of one minute.

28-215 *Condition of Arrester at Completion of Standard Operating Duty.*—At the completion of its standard operating duty the arrester shall be in the following condition:

a. The breakdown voltage of the series-gap shall not be appreciably altered.

b. The protective characteristics of the arrester shall not be appreciably altered.

c. The arrester shall be in condition to repeat its operating duty, though not necessarily indefinitely.

d. No part of the arrester shall be injured, either mechanically, electrically, or thermally.

### DIELECTRIC TESTS

28-220 *Standard Test Voltages.*—The standard test voltage for lightning arresters, except as otherwise specified, shall be an alternating voltage having an r. m. s. value as follows:

a. Lightning arresters rated at 600 volts or less—twice rated voltage plus 1000 volts.

b. Lightning arresters rated above 600 volts, 2¼ times rated voltage plus 2000 volts.

---

†In the present state of the art more accurate results can be secured by test on low voltage sections and extrapolating, than by direct test on higher voltage units requiring a voltage divider to use the oscillograph.

28-221 *Duration of Application of Test Voltage*—

a. For insulation consisting of porcelain, glass, or other similar vitrious materials the test voltage shall be applied continuously for one minute.

b. For insulation consisting of wood, paper, fibre, and other similar organic materials, whether or not impregnated, the test voltage shall be applied continuously for 10 min.

c. Standard arresters produced in large quantities for which the standard test voltage is 2500 volts or less, may be tested for one second with a test voltage 20 per cent higher than the one-minute test voltage.

28-222 *Conditions under which Dielectric Tests shall be made.*—

a. For arresters intended for indoor service and for all arresters rated at 600 volts or less, dielectric tests shall be applied with the arrester dry and clean, and at ordinary room temperature.

b. For arresters intended for outdoor service dielectric tests shall be made under precipitation of two-tenths in. (5.08 mm.) per min. at an angle of 45 deg. from the perpendicular with water having a resistivity as low as 7000 ohm cm.

c. When necessary for the protection of the characteristic element during test or in order to attain the test voltages herein named, a portion or all of the characteristic element may be removed during the dielectric tests. In case the characteristic element cannot be removed without also removing its insulating container, dummy container sections of similar characteristics, containing no characteristic element, may be substituted to the extent necessary to carry out the dielectric test.

28-223 *Where Dielectric Tests are to be Made.*—Unless otherwise agreed upon dielectric tests shall be made at the factory.

28-224 *Points of Application of Voltage.*—Test voltage of suitable value shall be applied between the following points.

a. With series-gaps short circuited (and characteristic element removed if necessary—see 28-222 (c)) the test voltage shall be applied between each line terminal and ground, and between each pair of line terminals.

b. With series-gap removed or sufficiently enlarged to prevent breakdown, voltage shall be applied across the terminals of the insulator or insulating material normally in parallel therewith. For the purpose of fixing the test voltage for this test the rated voltage of the insulation in parallel with the series-gap shall be considered to be two-thirds of the generated frequency breakdown voltage of the gap at its normal setting.

c. Insulators so located as to be subjected at any time to only a proportionate part of the voltage between line terminal and ground shall be assumed to be rated proportionately and shall be subjected to proportionate dielectric test voltage.

28-225 *Frequency and Wave-Shape of Test Voltage.*—The frequency of the test voltage shall be not less than 25 cycles per sec. A sine wave shape is recommended. The test shall be made with alternating voltage having a crest value equal to the square root of two times the specified test voltage.

28-226 *Measurement of Voltage.*—The voltage for dielectric test shall be measured in accordance with the section of the Standards entitled "Standards for the Measurement of Test Voltages in Dielectric Tests."

### CONSTRUCTION DATA

28-250 *Name Plate Markings.*—The following minimum information shall be given on the name-plates of all station and line type arresters for power service.

a. Manufacturer's name and address.

b. Manufacturer's type and designation number.

c. Voltage ratings (system and maximum).

d. Proper setting of series-gap if adjustable.

28-251 *Published Data.*—The following data in addition to information on the name-plate shall be given in manufacturer's publications:

a. Weight.

b. Amount of oil and/or other liquid required (if any).

c. Such dimensions as required for installation.

## CURRENT LIMITING REACTORS

### *Report of Subcommittee*

Two interesting developments in current limiting reactor practise involve the use of reactors which are oil-immersed in steel tanks. One development involves the use of a three-phase reactor, oil-insulated, self-cooled, while the other involves a single-phase unit, oil-insulated, and water-cooled. The advantages claimed for these designs are that foreign material cannot be drawn into the windings and that the equipment can be used with the highest factor of safety either for indoor or outdoor service.

The single-phase equipments are designed for installation as 22-kv. bus section reactors, introducing a reactive drop of 9.2 per cent when passing 90,000 kv-a. No live parts are exposed, as the coil is mounted in a steel tank, and lead covered cable is to be "wiped" to glands bolted to a junction box, which in turn is bolted to the tank. This method of attachment makes possible the removal of the reactor from the circuit without disturbing the "wiped" joints. Each cable terminal is so insulated that cable sheath currents cannot flow through the tank to ground.

The tank is provided with a conservator, pressure relief pipe, oil gage, thermometer, and standard gage trucks.

The magnetic flux of the reactor which would normally link the steel tank, causing large losses, is neutralized by utilizing the copper cooling coils as a short circuited winding, (the intake and discharge ends of the cooling coils being joined) thus acting as a flux shield. The potential developed in this shield causes a current to flow, which in turn develops an equal but opposite flux. Therefore, no flux enters the tank, and no losses are developed. The material of the cooling coils is a high-conductivity copper tubing of adequate cross-sectional area to permit such currents to flow as will develop the required flux. To neutralize the flux of the reactor coil the current in the shield is limited to a definite value by the inherent reactance of the cooling coils. The losses in the shield are limited by properly proportioning the cross-section of the shield.

### RELAYS

#### *Report of Subcommittee*

Three papers have been presented to the Institute during the current year under the auspices of this subcommittee as follows:

> *Developments in the Impedance Relay and its Application*, by H. A. McLaughlin and E. O. Erickson.
>
> *Application of Relays for the Protection of Power System Interconnections*, by L. N. Crichton and H. C. Graves.
>
> *A Carrier Current Pilot System of Transmission Line Protection*, by A. S. Fitzgerald.

The second paper listed was presented both at the Chicago and New Haven Regional Meetings.

The work of this year's subcommittee has consisted chiefly of reviewing the work of previous years and attempting to crystalize work which has been started. In this connection attention is called to the matter of standardizing relay acceptance test specifications. A group of last year's subcommittee submitted tentative test specifications in the annual report and expressed the hope that interested engineers would forward their comments to this subcommittee so that a tentative "Standard" could be submitted at this time.

Very few comments have been received and therefore it is thought advisable to submit the recommendation again with modifications herein:

The following acceptance tests are offered for consideration:

1. The complete name-plate data of the relay should be taken, including the name-plate data of its resistor, if it has one.
2. The relay mechanism should be carefully inspected to see that all parts function properly, and to insure that there are no loose screws or other parts.
3. The internal wiring of the relay should be checked to determine that it agrees with the specifications, and that the physical arrangement is satisfactory.
4. Dielectric strength tests should be made between each operating coil circuit and the other circuits grounded to the case, and between the trip circuit and the relay case. Tests should be made at 1500 volts, 60 cycles and should last for one minute.
5. The gap lengths between the various contacts should be measured to make sure that they agree with specified values.

A suggested specification is given below:

| Relay type | Minimum allowable gap | | |
|---|---|---|---|
| | Main contacts | Auxiliary relay contacts | Lever setting |
| *IA* | 1/16 in. | .... | 1 div. |
| *CO* | 1/16 in. | 1/8 in. | 1 div. |
| *CR* | 1/16 in. | 1/8 in. | 1 div. |
| *IK* | 1/16 in. | 1/8 in. | .... |
| Bellows | 1/4 in. | .... | .... |

6. The relay should be operated on all of its taps to make sure that it operates properly and in accordance with specifications.

Some typical specifications are given below:

a. Overcurrent relays should operate within five per cent of the marked tap values.

b. The directional element of directional relays should not move with either current or potential only applied.

c. The directional element of type *I K* power directional relays should operate at 3 volts (across the potential coil, excluding any resistors), 8 amperes (single phase, unity power factor), in 0.40 sec. or less.

d. The directional element of type *CR* power directional relays should operate at 3 volts (across the potential coil excluding any resistors), 8 amperes (single phase, unity power factor) in 0.25 sec. or less.

e. The directional element of type *CR* ground directional relays should operate at 110 volts, 0.5 ampere (single phase, unity power factor), in 0.25 sec. or less.

f. Directional relays should not rebound when the rated voltage is maintained on the relay while 50 amperes are interrupted.

g. Directional relay contacts should stay closed after making initial contact when closing under 50 amperes at rated voltage.

7. The relay calibration curve should be obtained on one tap only. The calibration curve should be carried up to at least five times the pick-up value of the relay. During this test it should also be determined if the relay chatters at the higher current values used. Chattering tests on bellows type relays should be made at 25 cycles, while on induction relays, rated frequency should be used.

8. After Test 7 is completed, the relay contacts should be examined to make sure that there is no pitting. It is sometimes found that contacts

have a tendency to freeze after several operations. In order to make sure that this does not happen, the tripping contacts should be made to make and break currents of values of the order they will make and break in service.

9. Tests should be made to determine that the operation indicator functions with currents of the magnitude available in service.

10. On directional relays the polarity should be checked. On a single-phase, unity power factor test, instantaneous polarity in the same direction on the current and potential coils should cause an *IK* relay to close its contacts, whereas, under the same conditions a *CR* relay should hold its contacts open.

11. Zero torque tests should be made to determine the absence of disk rotation with either potential only, or current only applied to the relay. When current alone is used, a value ten times the minimum tap setting should be used. The zero current test should be made with rated voltage on the potential coil.

12. The volt-ampere consumption and power factor, or the resistance and reactance of the various coils of the relay should be determined. This will determine the burden the relay will impose on its instrument transformers. Burden should be calculated on a 5-ampere basis for current coils, and on a 110-volt basis for potential coils. Measurements should be made at rated frequency.

13. Vibration tests should be made to determine that the relay will not close its tripping contacts when it is subjected to external shock or vibration. During this test the behavior of the operation indicator should also be noted.

14. Heat tests should be made on the relay coils to make sure that they will not exceed the limits specified by the A. I. E. E. Standards. The heat tests on the current coils should be made at rated current. The heat tests on the potential coils of power directional relay should be made at rated potential. The heat tests on the potential coils of ground directional relay should be made at 190 volts, and should last only for five minutes. The reason for this short time test is that under normal operating conditions the potential coils of such relays have no potential impressed upon them, but under conditions of ground, as much as 190 volts may be obtained in circuits whose normal voltage is 110.

15. The effect of ambient temperature upon the relay characteristics should be determined over the range of temperatures likely to be met with throughout the various seasons.

16. The effect of the surrounding atmosphere (excessive dampness, and fumes, etc.) upon the relay characteristics should be determined.

Another item discussed by this subcommittee during the last two years was the matter of name-plate data. In general it is agreed that the following information should be available.

a. Descriptive name of relay.
b. Nominal operating current, voltage, or both.
c. Frequency.
d. Manufacturer's type or style designation.
e. Manufacturer's name or trade mark.

In addition to the above the polarity of directional relays should have studs marked in the same manner as are terminals of instrument transformers. It is further recommended that the following information be available on the card which is usually attached to the relay when furnished.

f. Calibration curve or time setting chart.
g. Volt-ampere consumption and power factor (or resistance and reactance of the various coils).
h. Interrupting capacity of tripping contacts.
i. Resistance values of all resistances furnished with the relay. These values should also be stamped on the name-plate of the resistor.

As questionnaires are unsatisfactory and undesirable, a request is here made for comments on the foregoing.

During the past year many new relay developments have appeared.

The carrier-current pilot protective system has been called to the attention of the engineering fraternity by Mr. Fitzgerald who assures us that this system offers practically all of the advantages of the well tried pilot-wire system without its most undesirable features.

Induction type relays have been developed for use as power-factor relays, temperature relays, for control of reactive kv-a. meters, and for control of street lamp circuits by carrier current. Also a new induction type relay has been developed to perform on the impedance principle for transmission line protection. This relay has its restraining coil designed on the induction disk rather than the plunger principle.

A speed control relay is now used to facilitate the synchronizing of turbine driven generators. It has double-throw contacts operated by Warren synchronous motors through a differential gear in such a way that if one motor is faster than the other, one contact is closed, and, if slower, the other contact is closed. One motor is connected to the bus and the other to the machine being brought up to speed. The contacts control the governor and increase or decrease the machine speed until it corresponds practically to the bus frequency, at which point the machine may be synchronized by another relay or by the operator.

A new polyphase network relay has been developed and along with other things provides a most ingenious method of quickly replacing or testing the relay unit.

Attention has been called to the need of development of relays along certain lines and we set forth below the specific needs which have been mentioned:

1. A multi-contact relay of the plunger type of a size between the present overcurrent plunger

relay and the relay used as an oil breaker closing relay. This device should be either "latching" or "electric release." The contact head should be designed for a complete interchangeability of front and back contacts.

2. A d-c. voltage relay whose pick-up and drop-out values can be accurately adjusted, which will not be affected by a reasonable amount of vibration and whose calibration will not vary by "soaking" or by reversal of potential.

3. Further development of timing relays is suggested as they seem to be the most doubtful. The fan type is somewhat weak mechanically and is limited in length of time. The bellows type is difficult to adjust and will not stay in adjustment as it is easily affected by dirt, temperature, etc. There is considerable distance between the type enumerated above and the expensive motor operated devices. A need is felt for something in between.

4. For automatic transformer stations relays are needed which will measure the total station load. This often results in a requirement for a relay having adjustable back contacts for 50 per cent to 90 per cent of the operating value and having current coils capable of carrying continuously three or four times the operating value. Also these relays should have independent make and break contacts.

5. A reverse current relay is needed having greater sensitivity. For example, it is quite difficult to find a relay which will carry continuously the load current of a generator and yet will operate on the small reversal due to the machine motoring.

6. An impedance relay should be developed for ground protection where the ground current is less than the line load current. Three years ago Mr. W. W. Edson suggested using a *CZ* relay with the voltage restraining element reversed so that it could be operated by the residual voltage of a star-delta potential transformer bank.

Late in the year this subcommittee was charged with the duty developing Standards for Relays and the preliminary draft of September 1923 was resurrected to be worked over. This work has been started but the best that can be hoped for is to have a suitable foundation laid down for the successors of this subcommittee next year.

Along with this to the successors of this subcommittee is recommended:

1. A study of the operating experience due to the use of low-tension potential transformers for relaying high-tension lines where the voltage vectors are not an exact reproduction of what is taking place in the lines protected. The various compensator arrangements are too complex to be 100 per cent reliable.

2. Further study in the matter of relaying a transmission system having two parallel lines which may work in parallel or independently. Various cross-connected schemes will meet the parallel condition but they fail on the second. Pilot wires would be suitable but they are expensive. Impedance relays are not suitable for short sections of lines and they require special consideration when the expected ground currents are less than the load currents.

3. A study of the operating experience in the use of polyphase versus single-phase directional relays.

It is recommended that technical papers be obtained for presentation to the Institute of the three subjects named above.

F. L. Hunt, *Chairman.*

## Discussion

**K. B. McEachron:** In setting up standards for determining the protective characteristic of lightning arresters two points of view must be considered. First, what kind of duty is imposed by the surges which can come along connected circuits, and second, what can be produced and measured in the laboratory.

It seems probable based on field studies that voltages of the order of 2,000,000 volts may be reached in times of the order of 1 to 10 microseconds. The minimum time may be somewhat less and the maximum somewhat more than that given as no accurate measurements are yet available.

For a 220-kv. arrester this means, assuming 1 microsecond as the time to rise, a rate of voltage rise of 2,000,000/20 or 100 kv. per microsecond for each 11 kv. of rating. This it will be noted is the rate given in Section 28-202. Assuming, however, that the same potential gradient exists over an 11-kv. line half as high above the ground as the 220-kv. line, then the rate of potential rise will be 1000 kv. per microsecond or ten times the rate of voltage rise on the 11-kv. arrester as for the 220-kv. arrester when the transmission conductor is in the same electrostatic field.

It is feasible in the laboratory at the present time to produce impulses rising at the rate of 100 kv. per microsecond, but it is not feasible to produce impulses rising at the rate of 1000 kv. per microsecond, and yet have the wave front reasonably free from large oscillations.

If tests were made involving only potential rise, a wave rising at the rate of 1000 kv. per microsecond or 100 kv. in 0.1 microsecond might be obtained reasonably free from oscillations, but arrester testing requires the production of large currents in very short spaces of time which is not a condition conducive to steep rates of potential rise without excessive oscillations.

The traveling-wave theory states that the current in the traveling waves reaches its crest value at the same time that the voltage reaches its crest value. Going back again to the 220-kv. transmission line,—if the surge impedance be taken as 500 ohms and the arrester resistance also be considered as constant and equal to 500 ohms, then the current traveling in the conductor and through the arrester rises to a crest value of 2,000,000/500 or 4000 amperes in 1 microsecond. This assumes that the traveling wave has a crest potential of 2000 kv. and that the arrester is at the end of the line with no branch circuits.

In the present state of the art it is not possible to obtain a rate of current rise even approaching a figure of 4000 amperes per microsecond and still maintain reasonable freedom from oscillations and be able to record the phenomena on the oscillograph. To obtain such rates of current rise means little or no resistance in the circuit and very small inductance. Such a decrease in resistance means serious oscillation.

It seems desirable, therefore, to arrange the surge so that a current which is measurable and which can be obtained without excessive oscillations be chosen, and 100 amperes per microsecond seems about as high a rate as present methods and technique will allow. The crest value of 1000 amperes may in my opinion be subject to some variation, as for instance plus or minus 10 per cent, but the current should not decay too fast and the specification that the current shall decay to 500 amperes in a time not less than 10 microseconds is not unreasonable.

To specify a voltage wave when testing arresters is not sufficient because this only determines the breakdown voltage of the arrester. The second phase of arrester operation depends on the rate of current rise, the maximum current, and the duration of the current.

Since this is true it seems that the proper comparative test is to apply the same rate of potential rise, the same rate of current rise, and the same maximum current to all arresters, allowing the potential during this current flow to vary depending on the arrester itself and not on the impulse circuit to which it happens to be connected.

If impulse tests are to be made on insulation it is only necessary to consider rates of potential rise and a wave specified on the basis of maximum potential and time required to reach this potential would be sufficient as long as the breakdown occurs on the front of the wave. For such a test it would probably be desirable to specify also an exponential voltage rise.

For arrester testing such a specification is not sufficient. The maximum value of open circuit potential of the applied wave is not important. With the arrester the rate of voltage application up to the time when current begins to flow through the arrester is important, but what the voltage would have been if the arrester had not broken down has little or nothing to do with the characteristic of the arrester after it did become conducting. The remainder of the arrester performance after becoming conducting is dependent on the current-time relations. Thus sphere-gap measurements are not enough for the proper determination of the arrester characteristics, and I believe that it is a distinct step forward to specify the use of the cathode-ray oscillograph for the accurate determination of the arrester characteristics with respect to voltage, current, and time.

The manufacturer of lightning arresters does not make a practise of conducting complete tests such as outlined in the proposed standards on all arresters. Such complete tests are made on all new designs but it is felt that to take cathode-ray oscillograms, for instance, on all arresters would make an unnecessary addition to the cost of the arresters.

The proposed standards do give the user of lightning arresters a set of standards which when applied to arresters will allow him to make comparisons on a common basis which he has not been able to do in the past.

# Automatic Stations

## ANNUAL REPORT OF COMMITTEE ON AUTOMATIC STATIONS*

### INTRODUCTION

THE Committee on Automatic Stations was appointed by the Board of Directors, April 8, 1927. This, its first annual report, will give a general description of automatic station development during the past decade, and will enlarge upon some of the more important new features brought forward during the past year. Research, operation, standards, bibliography, and suggestions for future study will each receive attention.

### SCOPE

Broadly, the scope of work is comprised under automatic generating stations; automatic substations; and automatic station auxiliaries and the committee has complete jurisdiction over the apparatus that is associated with such installations and in the building or enclosing housings. Successful installations demand proper ventilation, temperature and moisture surveys, and with these, in addition to the various auxiliary apparatus associated with the control, the committee is concerned.

### RESEARCH

Research has been carried forward by operating and manufacturing companies with assistance rendered by several universities. The principal studies have been concerned with the operating requirements of devices for various classes of service. The number of cycles of operation per year for some of the more important devices has been determined.

Overcurrent relays, differential relays and other similar protective relays operate through about 300 or less cycles per year. Overcurrent circuit breakers in railway service may operate through as many as 1000 cycles per year. Load-limiting resistors may be introduced into circuits by the operation of their short-circuiting devices from 500 times per year in Edison Service to 100,000 or more times per year in interurban railway service. Regulating relays may be called upon to operate between 1,000,000 and 30,000,000 cycles per year. Other devices may be called upon to operate between the limits as given for overcurrent relays as an average minimum and regulating relays as an average maximum. Each application, particularly to automatic station service, requires a full knowledge of operating requirements in order to derive a maximum benefit from the particular device in its particular service.

Another field of research has been in the determination of the minimum protection required for various classes of power apparatus in automatic stations. The results of these studies are given in the Standards for Automatic Stations recently approved by the Board of Directors. Still another field for research has been in the study of operating conditions and requirements so that the automatic stations might be designed along simpler lines to give greater reliability and continuity of service. Valuable assistance has been rendered to the manufacturers by the engineers of operating companies. Several papers were prepared and presented by these engineers describing their experiences with automatic stations. This has stimulated the manufacturers toward the development of less complicated devices which give more reliable operation and permit better service to be rendered by public utilities.

### DEVELOPMENT

Development has been directed toward simplifying operating sequence, reducing the number of devices required for various classes of equipment, and making the operation more positive and reliable. Controls have been developed recently for power rectifiers. A brief description of the outstanding features of these designs is given later.

Supervisory systems for the control of remote power apparatus have reached a high state of development. Several papers indicating the trend of this development have been presented to the Institute. Many refinements have been incorporated and these systems are now considered to have an important field of application.

Telemetering is new. Only about a dozen systems including it are in service. Operating experience is needed. The state of development has not yet been passed. Several systems now being offered are simpler and more reliable than the older ones. They indicate that this important adjunct for automatic stations may soon be incorporated in standard designs.

### POWER RECTIFIERS

Power rectifiers are the latest type of power conversion apparatus to be used in automatic stations. These differ from the usual rotating power apparatus in that they have no inherent mechanical moving parts. They differ from the usual static power apparatus in that they require auxiliary features which have mechanical moving parts.

The power rectifier employing mercury is a static converter with a moving arc stream. The load responsive starting and stopping features of the control resemble those used for rotating synchronous converters. The methods used for starting and for stopping, and the protective measures resemble those used with static transformers having artificial cooling. Several features, however, are peculiar to the power rectifier. They are: (1) the rectifier must be ignited and (2) a relatively high vacuum must be maintained.

F. Zogbaum.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

Ignition of the rectifier is accomplished by a moving auxiliary electrode. Some schemes use alternating current for the arc starting. Some use direct current. When alternating current is used for ignition, two additional auxiliary starting electrodes are required. The ignition equipment is fully automatic. It starts the arc as soon as a-c. power is available. It extinguishes the starting arc as soon as the power arc is formed and maintained. It will re-ignite the rectifier automatically if for any reason the power arc is extinguished.

The required vacuum is usually maintained by two pumps. One is a rotary motor driven oil sealed mechanical pump; the other a mercury condensation pump. These start and stop in response to vacuum conditions as indicated by a vacuum relay.

Water cooling systems are usually favored for preventing the rectifier temperature rising above a specified maximum. It is controlled by conventional thermal relays connected in the operating sequence of the automatic switching equipment.

The minimum protection recommended for power rectifiers is less than that recommended for synchronous motor generators and synchronous converters, but is greater than that recommended for static transformers, synchronous hydroelectric generators, and synchronous condensers.

Protection against a-c. undervoltage, single-phase starting, and single-phase operation is sometimes required for power rectifier auxiliaries under certain conditions. Protection against severe a-c. over-current is generally required. It may be self-resetting in the case of power rectifiers, while it is usually of the lock-out type for rotating machines. This is due to the difference in the inherent characteristics of the two machines. Protection against d-c. reverse current and excess temperature due to sustained overload is provided for the power rectifiers just as for rotating power apparatus. Power rectifiers, unlike most other types of power apparatus, are usually provided with protection against poor vacuum, failure of vacuum pump, and failure of cooling fluid supply.

The starting and stopping of power rectifiers in automatic stations follows the same principles as developed for rotating machines. Some device substitutions are made in the protective circuit to suit the individual characteristics of the rectifiers. Similarly, load-limiting and load-shifting features may be provided just as for rotating machines, particularly synchronous converters.

In general the automatic control for power rectifiers is similar to that for rotating machines, excepting where it has been necessary to develop some special devices to suit the peculiar characteristics of the rectifiers just as it was necessary to develop special devices for some of the peculiar characteristics of synchronous motors, d-c. generators, synchronous converters, and other types of power apparatus.

### SUPERVISORY EQUIPMENT

Supervisory equipment is rapidly assuming an important place in the design of electric power systems. It is being used not only for the supervision of automatic stations, but for the supervision of important power distribution networks and the operation of large substations and generating stations. The trend is definitely toward a simple system normally at rest. Any operation either to actuate a device or to report an actuation starts a sequence. This usually continues until the operation and report are completed. Then the system remains at, or returns to, a position of rest.

Three or four line wires continue as standard for supervisory systems with visual indication of operation and the usual operating currents and frequency. Carrier-current systems use either one or two wires, or, in some cases, are superimposed on power circuits. Each method has a field of application depending upon local conditions and operating requirements.

Several designs of supervisory equipment use the ordinary telephone apparatus and telephone communication circuit for both talking and control, as well as answer back. These have a relatively restricted application.

Reliability of supervisory systems and equipment is only as good as the line wires which are provided. The terminal apparatus may be perfect. It may operate precisely as the designer intended it to operate. Yet, if the wires connecting the terminal equipments fail, the entire system is rendered inoperative. It is necessary that this feature of supervisory equipment be taken into account in its application, since it has shown a definite limit for such systems under present day operating conditions.

### TELEMETERING

Telemetering is just coming to be recognized as a distinct necessity in the operation of automatic stations, particularly those forming part of large electricity supply systems. Developments have been rapid during the past two years. A number of systems is on trial, most of them too elaborate for economical application. Some give promise of meeting the requirements of high accuracy, low cost, reliable operation, and freedom from resistance and other circuit errors.

The telemetering systems now in operation are used for a very wide variety of purposes. Some give readings of circuit current and voltages. Some give readings of station load. Still others are used for transmitting to a central office, the readings of total station loads, and also for again totalizing all the stations on a system and returning this total to each of the contributing stations.

Still other systems are used for giving a central dispatcher knowledge of the distribution of demand over a given system. Others serve to adjust the supply of power from two sources in proportion to the load demand required from these two sources.

In another year, operating experience should be available which will permit a better picture of the trend of this very interesting development to be given more definitely.

### CARRIER CURRENT

Carrier currents in frequencies from 500 cycles to over 50,000 cycles are being used for the operation of supervisory and telemetering systems. Some of these are used in combination with automatic stations. Some are used for the operation of power apparatus in remote stations. Several papers have been presented to the Institute on this subject and the discussion of these papers gives the trend of thought. A great deal of research and development work is being done on this subject and future reports will no doubt be able to give more comprehensive data concerning it.

### OPERATING EXPERIENCE

Operating experience, particularly that with automatic stations, has formed the subject of several papers presented before the Institute. The art would advance very much more rapidly and more surely if more operating engineers would take it upon themselves to present to the membership, through papers read at regional meetings, their individual experiences with automatic stations. The manufacturers and designers recognize that each power system has its individual characteristics. These require the fitting of automatic stations, individually to each power system. Notwithstanding these facts, all systems have a certain similarity. They also have certain operating requirements. The art is handicapped because the designers do not obtain freely from the operators the system requirements and performance under given conditions. A number of the operating engineers have contributed richly toward the development of the art by telling of their experiences. It is believed that a broadening of this idea will do much to stabilize the industry.

### MAINTENANCE AND INSPECTION

Maintenance and inspection of automatic stations are prime requisites for their successful operation. To obtain a maximum benefit from these stations it is necessary that they be given adequate, systematic, and intelligent inspection. The word "intelligent" really covers the field, for, in a broad sense, it includes the words "adequate" and "systematic."

Much of the development work carried on by the manufacturers has been with the idea of reducing the necessity for maintenance and inspection to a minimum. The devices and schemes of operation which have been produced from this development render the automatic station a unit in any system, which not only contributes to the economic operation of that system, but which also does much to promote continuity of the service supplied by that system.

Practical analysis verifies the statement that "Nothing is perfect." Any commercial device is a compromise between perfection and cost. The quality of service to be expected is thus necessarily a measure of the maintenance required to affect those things by which a device or an equipment as a whole fall short of perfection. If the outage of a unit is not a serious matter, time may be allowed for clearing a failure in the switching sequence. This would normally render the unit inoperative under certain conditions; hence there might be a tendency to neglect the matter of routine inspection or maintenance.

In protective devices, however, the failure which might result in costly damage as well as extended outage is a far more serious matter. For this reason, the automatic station is safeguarded by protective devices not ordinarily found in attended stations. In protecting against equipment failure, one protective device is often reenforced by another, so that only by simultaneous failure of separate and independent protective devices can serious damage be done to the equipment. These protective devices are the product of many years of research, development, and experience. It is necessary, however, that they be used intelligently. They must be suitably adjusted and adequately maintained if it be expected that they render the service for which they were intended.

The importance of continuity of service renders the proper functioning of switching sequence of equal importance with that of protective equipment. A knowledge of the proper functioning of each device and its relation to other devices is the first qualification for one responsible for the inspection or maintenance of an automatic station. Such an individual need not be a technically trained man; in fact, often he is not. He should, however, have a thorough grasp of the fundamentals, and have experience not only in the operation of the equipment itself, but in the relation of the station to the rest of the system. The latter is essential if he is to be able to analyze properly the limitations of the equipment and make adjustment of it accordingly.

With each equipment the manufacturers usually supply instruction books and diagrams giving a comprehensive analysis of the scheme of operation, as well as detailed information of each device. If he is to give the station the best attention an inspector, or maintainer, should be thoroughly familiar with the contents of the instruction book and wiring diagram.

Sometimes the maintainer overdoes his job in such matters as cleaning and filing of contacts. Relays are usually under covers. Inspection of the parts is facilitated by the use of glass, making the removal of the covers necessary only at infrequent intervals. The removal of oxide from contacts is accomplished by the use of crocus cloth, or cleaning with carbon tetrachloride. Contacts in the power circuits and the heavier duty control circuits, when properly adjusted, will require little or no dressing of the contacts. They should be kept clean and bright. Filing is usually not required, as the contacts wear naturally to better surfaces than may be effected by filing. Unless carefully done, filing tends to make matters worse, and even shortens the life of the contact.

Judicious lubrication of moving parts, cleanliness, and the keeping of wiring connections and interlock adjustments tight are the principal factors having to do with the proper maintenance and inspection.

The frequency of inspection of any particular station is best determined by those in responsible charge of the systems. The experience of others in the operation of similar equipment in like service may be used as a guide, but seldom serves as a standard to be followed, since operating conditions are never identical. A brief experience with an inspection schedule will determine where it should be modified so as to give best results. An inspection report made in preliminary fashion with mimeograph copies might well be used during the the first few months until a definite plan is decided upon. Samples of inspection report forms used by a number of operating companies are now available and may be had upon request from them.

A summation of the situation is given by a member of the committee who has had a number of years of experience in the operation of automatic stations. He states that several years of experience with daily inspection, not having a definite routine, did not produce the required results. Railroad equipment is operated on a car or locomotive mileage basis as determined by the conditions. It is then taken into the shop, thoroughly overhauled and sent out on the road subject to a trip of casual inspection somewhere on the road, until it has operated a certain mileage. Then it is returned again to the shop for general inspection. It is logically assumed that after such an inspection, it should cover a predetermined number of miles without attention. The same assumption can be accepted for the inspection of automatic station equipment. There should be a periodic thorough inspection; weekly on some parts of the equipment and monthly, semi-annually, or annually on other parts. Rotating equipment may have to be cleaned at intervals of two or three days,—or even longer,—depending upon the number of hours run and conditions of ventilation of the station. The station may have to be visited daily for other reasons than inspection of apparatus where no supervisory equipment is used. With supervisory control, no other attention should be needed than cleaning and periodical inspection.

### STANDARDS

A final report on Standards for Automatic Station No. 26 was presented to the Standards Committee at its January 20, 1928 meeting. Following a letter ballot, this report was submitted by the Standards Committee to the Board of Directors with the recommendation that it be approved as an A. I. E. E. Standard. The Board of Directors approved the Standards for Automatic Stations, April 6, 1928.

The Committee on Automatic Stations intends to present revisions of these standards to the Standards Committee from time to time as the necessity for them may arise.

### FUNCTIONAL NUMBERS

Functional numbers have been used for automatic station devices and functions for about 15 years. A gradual standardization has resulted. The latest list is given in the Standards for Automatic Stations recently adopted by the Board of Directors.

The functional numbers initially followed the sequence of operation of the devices. Later, as automatic stations developed, this sequential numbering could not be followed. It resulted in an arbitrary numbering system which has become generally known in the art.

The present numbering system uses a base of not more than two digits. The numbers from 1 to 99 inclusive cover the entire range of basic functions. Numbers in the 100, 200 and other series are used for designating these functions when used with feeders, supervisory systems and the like. The system of numbering the functions, however, still remains arbitrary.

It has been thought that a system of numbering more logical and less arbitrary might be developed. A subcommittee has had this matter under consideration since December 1, 1927. They have rendered several reports. Progress has been made, but a solution has not yet been supplied. It is recommended that a subcommittee be appointed to continue the study of this important topic during the ensuing term.

### PAPERS

Papers presented under the auspices of, or in cooperation with, the Committee on Automatic Stations during the current year have been as follows:

| Subject | Author | Place & Date |
|---|---|---|
| Operation and Performance of Mercury Arc Rectifiers. | Caesar Antoniono | Chicago–Nov. 1927 |
| Automatic Control of Edison Systems................ | O. J. Rotty & E. L. Hough | New York–Feb. 1928 |
| Automatic Switching of Incoming Lines and Transformers.................. | A. E. Anderson | St. Louis–March 1928 |
| Mercury Arc Rectifier Substations................. | G. E. Wood | New Haven–May 1928 |

### UNFINISHED BUSINESS

Topics which have been under consideration by the committee and concerning which no report has been rendered are as follows: (1) Ventilation; (2) Fire protection; (3) Economical construction; (4) Unusual operation conditions; (5) Load dispatching; and (6) Wire designations.

In addition to these items of unfinished business, there are other items upon which reports have been rendered but which do not fully close the subject. These are as follows:

(1) Papers, (2) Standards, (3) Research, (4) Operation reports, (5) Remote metering, (6) Supervisory control, (7) Progress in the art, (8) Inspection, (9) Functional numbers, and (10) Bibliography.

It is recommended that these subjects be given consideration by the succeeding committee.

### BIBLIOGRAPHY

Many requests have been received from time to time for a bibliography on automatic station literature. Such a bibliography has been prepared and forms an appendix to this report. It is recommended that future committees add to this bibliography so that there may be found available in the TRANSACTIONS of the Institute a comprehensive bibliography on the subject.

## Bibliography of Automatic Station Literature

# General Power Applications

## ANNUAL REPORT OF COMMITTEE ON GENERAL POWER APPLICATIONS[*]

*To the Board of Directors:*

Your Committee on General Power Applications endeavored to perform the following functions:

1. Keep in touch with all developments relating to general power applications.

2. Foresee the need for development of new electrical apparatus to meet new conditions in general power applications.

3. Develop papers to be presented before the Institute on subjects relating to general power application.

4. Present a report at the end of the Institute year recording the development of general power applications during the preceding year.

To accomplish the first function, a review of the technical press was undertaken, each committee member being asked to review certain periodicals. To be successful, a review of this type requires the sacrifice of considerable time from our daily occupations and is not extremely fruitful in results even if such review is punctiliously observed. However, we were fairly successful in this endeavor.

The second endeavor mentioned above is the hardest of all to attain but is one which, if successful, would add much to the value of the committee.

The third endeavor has brought out many suggestions for prospective papers. These include the following:

High Cycle Equipment for Portable Tools.
Telephone Central Office Power Plants.
Short Circuit Protection for Industrial Installations.
Overload and Single Phase Protection for Across-the-Line Squirrel-Cage Induction Motors.
Application of Power and Control Equipment to Power Plant Auxiliaries.
Across-the-Line Starting of Induction and Synchronous Motors, Including 2200 Volt Application.
Improvement of Ward Leonard Control with Special Reference to Application to Elevators.
Mass Production of Electric Light Bulbs.
Storage Batteries, Improvements and Applications.

Instead of enumerating a large number of new applications, only representative ones are cited in this report. Details of these are more specific than formerly and we feel that in drawing these to the attention of the membership, we shall have focused their attention on the general trend of all applications. Necessarily, there are many types not mentioned, either because the committee has no access to such, or because their application is somewhat similar to others.

The thanks of the committee is extended to the Allis-Chalmers Mfg. Co., American Telephone & Telegraph Co., Bethlehem Steel Co., D. H. Braymer Equipment Co., Canadian General Electric Co., Century Electric Co., Consolidated Gas, Elec. Lt. & Power Co. of Baltimore, Cutler-Hammer Mfg. Co., Duquesne Light Co., Edward Ford Plate Glass Co., Electro-Dynamic Co., General Electric Co., Graybar Electric Co., Howell Electric Motor Co., Lincoln Electric Co., Louis-Allis Co., The Management Engineering & Development Co., Ohio Bell Telephone Co., Philadelphia Electric Co., Reliance Electric & Engineering Co., Stone & Webster, Westinghouse Electric & Mfg. Co., J. D. White Engineering Co., the Universities of Missouri, Massachusetts Institute of Technology, Purdue and Toronto, firms with which committeemen are connected or whose cooperation and publications we have made use of in compiling this report.

### MARINE EQUIPMENT

At the close of the year 1927, there had been placed in commission, or were under construction, a total of 118 electrically propelled vessels of various types, ranging from river towboats and small yachts to the largest types of sea-going ships. The equipment of these crafts aggregated more than 700,000 shaft hp., about 92 per cent of the primary power being supplied by turbines and 8 per cent by Diesel engines.

The outstanding event of the year was the completion and installation of turbine-electric propelling equipment for the Panama Pacific Liner *California*, Fig. 1, the largest passenger ship ever built in the United States and the largest electrically driven ship of her class in the world. The *California* is a twin-screw ship with a displacement of 30,250 tons at load draft.

The maximum energy delivered to her propeller shaft is 17,000 shaft hp. and a speed of 18 knots can be maintained with this power input. At the cruising speed of 16.5 knots, the output of the turbo generator is 13,500 shaft hp. and at this speed the ship has a cruising radius of 15,400 mi.

The propelling equipment comprises two 16 stage steam-turbo generators, each having a maximum capacity of 6600 kw. at 2880 rev. per min. This power is transmitted to the propeller shafts by means of two synchronous induction type motors having a continuous maximum rating of 8500 shaft hp. at 120 rev. per min. These motors are direct connected to

*Presented at the Summer Convention of the A. I. E. E., at Denver, Colo., June 25-29, 1928.*

the propeller shafts and are reversible so that no reversing turbines are required. Both propelling motors can be operated at about ¾ of their rated output by the current supplied from one of the two turbo generators, thus insuring economical cruising at reduced speed.

The *California* was launched October 1, 1927 and work on a second ship of the same size, to be provided with electric propelling equipment of the same power, is already under way.

*Diesel Electric.* While the primary power supplied by Diesel engines is comparatively small compared to that supplied by steam turbines, yet there have been a number of notable applications of Diesel-Electric Drive for marine work.

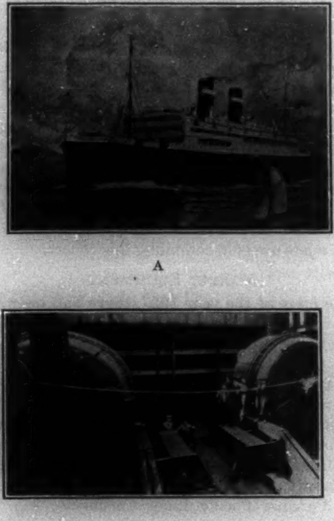

FIG. 1—A. TURBINE-ELECTRIC-PROPELLED LINER *S. S. California*

B. VIEW SHOWING THE INSTALLATION OF THE MAIN PROPULSION MOTORS

One of these in which d-c. apparatus is used is the Coast Guard Cutter *Northland* which is now serving on patrol in Alaskan waters.

The main engine room equipment consists of two Diesel engine-driven generators, each rated 410 kw. 250 volts at 200 rev. per min. These supply current to a double-unit type, shunt-wound propeller motor, Each section of this motor (Fig. 2) is rated 500 hp. at 120 rev. per min. The ship will develop a speed of 12 knots with her single propeller operating at 120 rev. per min. and the motor developing 1000 shaft hp. The control is located in the engine room and is of the variable voltage type.

There are some unusual features in the propelling equipment, one of them being the use of a magnetic clutch between the motor and the propeller shaft. Under normal conditions the motor and shaft are rigidly bolted together, but when cruising at reduced speed in the ice fields the bolts will be removed and the power transmitted through the magnetic clutch. This will transmit a torque equivalent to 500 shaft hp. at 95 rev. per min., but any increase of load beyond this rating will cause the clutch to slip and will thus prevent dangerous stresses.

Other applications of Diesel-Electric Drive include that on four large double-end Diesel-electric ferry boats made for the Southern Pacific Company for service in San Francisco Bay, electrically propelled packet boats running between points in and around New York Harbor and cargo boats recently open to Diesel electric propulsion by the U. S. Shipping Board. Another novel application of Diesel-electric drive was inaugurated by the Bureau of Light Houses by its decision to adopt this method of propulsion for three new light ships. These ships are at anchor most of the time but in severe weather, the propulsion equipment will be used to take the strain off the anchor chains and to maintain the position of the light in the event of the breaking of the moorings.

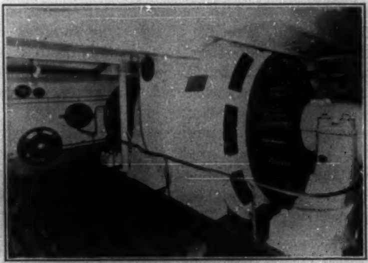

FIG. 2—U. S. COAST GUARD CUTTER *Northland's* 1000-HP., 120-REV. PER MIN., 500-VOLT DOUBLE ARMATURE PROPELLER MOTOR

*U. S. Navy.* The Washington Arms Conference in 1921 served to greatly emphasize the consideration of the relative value of weight and space for power apparatus on board ships. Recent designs of machinery have shown a marked advance over previous practise in the matter of lightness and compactness without sacrifice of strength or reliability. This has been made possible by the use of light metal alloys and the use of fabricated steel parts to replace the original cast iron parts. Cast iron is not only too heavy a construction, but is also unreliable under such shocks as are imposed by battle conditions. The chief developments in application in the past year have been along the lines of building machines to meet the peculiar needs of the application.

A notable application is that of a 200-hp., 5000-rev. per min. d-c. motor on which the Navy Department has recently completed tests. This motor is used to drive a three-phase blower type compressor having a capacity of 3200 cu. ft. and a discharge pressure of 10 lb. Special precautions had to be taken to balance this armature, the peripheral speed of which is approximately 20,000 ft. per min. The bearings are flood-lubricated, the oil being supplied by a separate motor-driven pump. The method of cooling is novel, the cooling air being that which is drawn through the motor into the first stage of the compressor.

## ELECTRIC RAILWAYS

The applications in the electric railway field were concentrated mainly upon the modernization of rolling stock. Existing cars were replaced with equipment better suited to modern transportation requirements, including motors and control of the latest design.

*Oil-Electric Locomotives.* Interest in the application of oil-electric locomotives continued throughout the year and a number has been put in service. These demonstrate the economies and other operating advantages of this type of drive. Two 100-ton units are now in heavy switching service on the Erie Railroad and 60 ton units were completed for the Chicago & Northwestern Railway, the Union Carbide Company, and the American Rolling Mills Company. Work is also proceeding on oil-electric, freight and passenger locomotives for the Putnam Division of the New York Central Railroad and a 300-hp. oil-electric motor car is ready for service.

*Gas-Electric Motor Cars.* One of the large automotive truck manufacturing concerns has recently announced the completion of car units consisting of gasoline engines and electric generators, to be used with an electric drive to furnish power for virtually any kind of transportation. This is unique in that a single base contains all the power equipment and accessories except the gasoline tank, the radiators and such electric motors as may be used in driving the axles. An important application is expected to be railway transportation. More than one power unit can be used, ranging from a single day coach moving along the rails without the help of a locomotive, to a six-car commuter train in which the cars at each end of the train contain power units. By means of a system of remote control, these units can be operated by an engineer at either end of the train.

*Special Type Locomotives.* A new combination trolley and storage battery type of locomotive has recently been placed in service by the Chicago, North Shore and Milwaukee R. R. These locomotives may be used either on the trolley system, or on tracks not now equipped with trolleys. The motors are ventilated by electrically driven fans. D-c. control is provided for either trolley or battery and transfer from the trolley to the battery power is automatic. Motor-generator sets are used for charging the battery when running from the trolley.

*Automatic Substations for Railway Signaling Power Supply.* The continuous inductive type of automatic train control provides a new field for the application of small frequency-changing motor-generator sets and automatic control for starting the sets and for connecting the generators to the load in the shortest time possible. Power is supplied to the train control system at a frequency of 100 cycles in order to eliminate inductive interference from commercial circuits.

Motor-generator sets provide the 100-cycle power from 25 or 60 cycle primary sources. The motor-generator sets range in size from 1.5 kv-a. to 60 kv-a. The rating depends primarily upon whether the power is to be used for both automatic train control and automatic block signaling or only for the former.

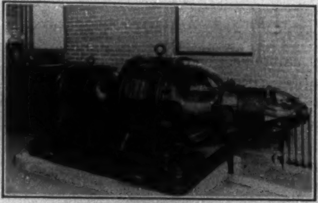

FIG. 3—MOTOR GENERATOR SET

A very interesting installation of automatic substations to provide 100-cycle current for the operation of both automatic block signaling and automatic train control is on the Pan Handle Division of the Pennsylvania R. R. system between Pittsburgh, Pa. and Newark, Ohio. This division consists of 158 route mi. or 375 track mi. Eight automatic substations are provided, the maximum distance between any two adjacent stations being 36 mi. and the minimum five miles. Each station, excepting one, contains a 60-kv-a. 80 per cent power factor, 220-volt, single-phase, 100-cycle alternator, with direct connected exciter, driven by a direct connected 75-hp., 220-volt, three-phase, 60-cycle, squirrel-cage induction motor with the necessary automatic switchgear. Fig. 3 shows one of the seven motor-generator sets and Fig. 4 shows one of the automatic switchboards. The motor starter is in the foreground, next are two feeder panels, one to feed east and the other to west. Next is the relay panel followed by the voltage regulator panel. The panel in the background is for the control of the two motor-driven air compressors in the extreme background and is not part of the automatic switchgear.

## MINING INDUSTRY

A new type "sealed equipment" cable-reel-gathering locomotive has been provided for mine application and is provided with two 30-hp. motors, contactor control of the progressive series parallel type, and a motor-driven cable reel with 450 ft. of double-conductor, concentric, rubber-covered cable.

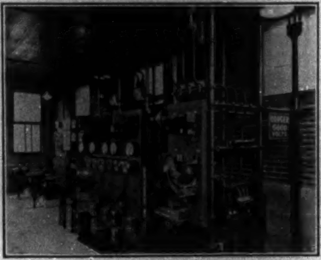

FIG. 4—AUTOMATIC SWITCHBOARD

The traction motors, the cable-reel motor, cable-reel collector rings, control, headlights, and all parts of the equipment with the exception of the trolley pole and the reel cable are completely enclosed in strong cases which are designed to prevent any gas explosions that occur within these cases being transmitted to the surrounding atmosphere. With the exception of short sections of cable leading to the motor, where flexibility is necessary, all wiring is enclosed in rigid type conduit, securely anchored and provided with steel fittings where it enters the various compartments. Flexible motor cables are enclosed in heavy rubber hose, the ends of which are also provided with steel fittings; Figs. 5 and 6 show views of this type of locomotive.

FIG. 5—ELECTRIC MINE LOCOMOTIVE

*Quarry Locomotive Cars.* An interesting system of remote control for locomotive cars operating on quarry tracks was developed. With this system a single operator, located in the tower-control station, from which he can see all the cars, is able to start, stop, and even to switch cars on different tracks. Electrical equipment of the cars consists of high-torque squirrel-cage motors provided with solenoid brakes and controlled through a pair of reversing contactors which throw the motors on the line at full voltage. Two current-collecting shoes are used for making contact with two "third rails" located between the traction rails. The separate tracks on which these cars operate have isolated circuits or the cars can be maneuvered on a loop track with isolated sections.

FIG. 6—INTERIOR VIEW

The control operator handles the cars from a pilot switch which actuates the reversing contactors and, when the current is shut off, the solenoid brakes set automatically and retard the car, torque being adjusted for smooth retardation. The application of this system is expected to speed up production and reduce operating cost, inasmuch as one operator can in this way handle several cars whereas with the old system an operator was required for each car.

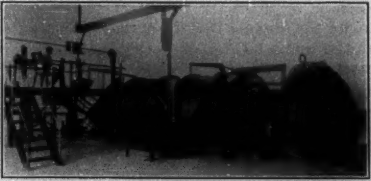

FIG. 7—3200-HP., 79 REV. PER MIN. D-C. HOIST MOTOR

*Largest Hoist Motor in Western Hemisphere.* We are continually having our attention called to the ever increasing size of electrical equipment being used in the industries. One of the large electrical manufacturing companies is building for the Frood Mines of the International Nickel Company of Canada a 3200-hp., 79 rev. per min. d-c. hoist motor. On both the horsepower and torque rating, this motor is larger than any single mine hoist motor yet installed or selected for mine hoist applications in this hemisphere. Fig. 7 illustrates this motor.

Its armature will be 144 in. in diameter and power for the motor will be supplied by a fly-wheel motor-generator set consisting of a single a-c. motor driving two 1250-kw., 600-volt generators. The hoist has cylindrical drums 12 ft. in diameter and is of the balanced skip type for the handling of ore from a maximum depth of 3000 ft. The load will vary with the depth and at 2000 ft. the skip will handle 10 tons of ore at a speed of 3000 ft. per min.

This equipment will employ the variable voltage d-c. system of speed control.

*Improved Equipment for Gaseous Mines.* In gaseous coal mines an explosion of gas may occur, this explosion be communicated to the fine coal dust deposited on the sides, roof and bottom of the mines, thus extending and materially augmenting the initial explosion and, perchance, causing a disaster of large proportions. In order to prevent the gas explosion communicating with the coal dust, the latter is covered with rock dust which is distributed to the walls, roof, and bottom of the mine under air pressure. Fig. 8 shows a machine used for this purpose. The rock dust is contained in the hopper at one end of the machine and is distributed by the motor-driven blower. This equipment is capable of delivering the rock dust through several hundred feet of hose to entries on either side of the track. The blower delivers a constant volume of air at a fixed velocity regardless of the length of hose.

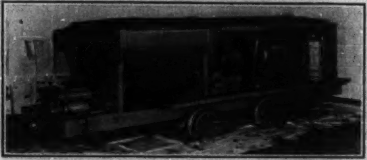

Fig. 8—Machine for Distributing Rock Dust

The electrical equipment is especially designed for use in gaseous mines and has been approved by the Bureau of Mines for this application. It consists of a 20-hp. permissible type motor and control. The motor has solid rear brackets and bronze screw type inspection covers on the commutator end. The controller is of the full magnetic push button type. The contactors, overload relay, starting resistor, and push button are all enclosed in a single case arranged for easy inspection of the equipment.

By using the packing gland type of lead entrance the electric cables can be run without external connection from the inside of the motor to the inside of the controller. The design results in a very simple method of mounting and wiring the electrical apparatus. The push buttons which are enclosed in the case are operated by two plungers extended through the case and protected by a housing cast integral with the top of the control.

*The Largest Mine Locomotive.* The largest single unit underground mine locomotive was exhibited at the American Mining Congress Convention in May. This locomotive weighs 38 tons and has the following limiting dimensions: Gage 35 in., height 46 in., width 64½ in., overall length 24 ft.-0 in. The locomotive is equipped with three 133-hp., 500-volt motors or a total of 399 hp. per locomotive. The motors are arranged for forced ventilation from a separate blower motor. The control is of the semi-magnetic type, series-parallel with overload relay and no-voltage protection.

The locomotive was designed for a haul of approximately four miles with an average grade of approximately 2.4 per cent and a maximum grade of 5.6 per cent for a thousand feet and will haul an average of 50 cars per trip and make 9 trips in 8 to 8½ hr. The car weight loaded is approximately 3½ tons average. Fig. 9 illustrates the locomotive.

## GLASS INDUSTRY

The application of motor drive in the glass industry is of course not new. The excessive demand of thin plate glass of the non-shattering type, and for ordinary thin plate, such as used in the auto and allied industries, has caused a general building and rebuilding program for this type of glass manufacturing.

The use of electrically driven mechanisms at practically every step and the fine instruments required as well as powerful cranes, etc., has created a great and growing demand for motors, controllers, and general equipment to improve the methods of manufacture of thin plate glass.

Fig. 9—Largest Mine Locomotive

## ELECTRICAL REFRIGERATION

The enormous growth of motor application in the field of electrical refrigeration is indicated by the fact that ten years ago this industry produced about 1200 units a year, whereas the year 1927 produced 1,500,000 units.

The introduction of the electrical refrigerator into the home has added during 1927 a revenue of $3,000,000 to the Power Companies' earnings.

An interesting application in this field is the use of single-phase motors mounted in rubber. All single-phase motors have an inherent double frequency torque pulsation which gives rise to some noise and vibration. Fig. 10 shows a 1/30 hp. split-phase motor of the usual construction but with this unusual mounting.

The base of the mounting has vertical supports going up through the ventilating holes in the bottom of the end-flanges of the motor and offset around the shaft so that the top of the support is directly over the shaft and some distance above it. There are two holes in each support, one above and one below the shaft with rubber bushings in these holes. Two pins extending inward from the end-flange engage these rubber bushed holes and support the motor. The motor is thus supported entirely from these pins in the end-flange and there are no metal-to-metal contacts between the motor and its mounting. This rubber mounting has two advantages over a rigid mounting in that it eliminates a large part of the vibration normally transmitted to the apparatus on which the motor is mounted and it also reduces the usual motor noise to a minimum, as the motor can produce noise only by vibration in the relatively small surface of its own frame.

In this field also, it is interesting to note the application of what is essentially a two-phase motor from a single-phase line, one phase of the motor being connected directly across the source of supply and the other phase connected in parallel with the first phase through a capacitor. In order to secure best operation, it has been found desirable to make a change in connections on the capacitor as the motor comes up to speed. This change is made by the use of a single centrifugal device which operates a single-pole double-throw switch. Due to the fact that it has no commutator or brushes, it is extremely quiet and causes no radio interference except one slight click when the centrifugal switch operates. The fact that the motor operates as a polyphase motor has a tendency to eliminate the characteristic hum of a true single-phase motor.

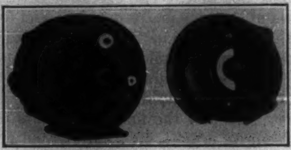

Fig. 10—Split-Phase Motor Frame with Cushion Base

### Paper Mill Industry

A new application in the manufacture of paper is that of an adjustable speed motor to a paper winder. This drive consists of a direct connected variable speed motor and the necessary control equipment. The motor is designed to give a speed range of 4 to 1 by voltage control and to give a crawling speed for threading the paper by means of armature resistance. This particular drive was supplied at the mill of the Fraser Co., Ltd. at Madawaska, Maine, and has caused a great deal of favorable comment because it is an economical arrangement when viewed from the standpoint of first cost and has proved a very satisfactory arrangement from an operating standpoint, all the features having been combined in it which are ordinarily secured only through a Ward Leonard system of speed variation.

### Electric Furnaces

For a number of years the wrought brass industry, concentrated in a comparatively few large plants, has used electric arc and induction furnaces almost exclusively for melting copper-zinc alloys. The cast brass industry, consisting of many small plants widely scattered, has been slower in the adoption of electric heat for melting but there was an increased use of electric furnaces for melting brass for castings. The brass industry as a whole uses comparatively small melting units, 75 to 200 kv-a., all single phase. There appears to be less objection than formerly on the part of public utility systems to single-phase loads of this character, and units as large as 300 kv-a. have been installed.

In the steel industry the use of the three-phase arc furnace of the three-electrode type followed the standard practise of the last two or three years and "electric steel" has now become a trademark to indicate a superior quality of steel.

There is a decided growth of interest in the possibilities of cast iron of uniform analysis and of definite physical properties. This is one of the most promising applications of the electric melting furnace.

The coreless type induction furnace, generally referred to as the "high-frequency furnace," entered the ferrous field for the production of high grade alloy steels. Completed equipment of this character included a 150-kv-a., 900-volt, 2000-cycle unit for melting steel, 1 60-kv-a., 900-volt, 960-cycle unit installed for laboratory service in a large steel plant, and a 187-kv-a., 900-volt, 800-cycle unit shipped to Sweden. All of these units consist of a motor-generator set, using a three-phase motor of standard frequency and voltage to drive a single-phase high-frequency generator, together with the corresponding high-frequency capacitor units.

In the December 16 number of the *Electrical Review*, London, there is an article on a high-frequency steel furnace, this furnace being operated by a 150-kw. motor-generator set and used for only the very finest steel. This appears to be another application of electricity which betters the product and does away with a great deal of hard exacting labor, inasmuch as it is the first radical departure from the primitive coke furnace for making crucible steel. This furnace is in operation at the Imperial Works of Messrs. Edgar Allen & Co., Sheffield, England.

### Steel Mill Industry

*Automatic Steel Mill.* A great improvement in the rolling of steel was inaugurated during 1927 which has made it possible to roll the "H" shaped beam so desirable for columns in buildings. The improvement consists in using sets of rolls to roll simultaneously the flanges and web of the beam. The adjustments of all of the rolls is made automatically at the same time. Important new features were also developed for the motor driving these rolls.

Fig. 11 shows the main motor room for the new mills at the Homestead plant of the Carnegie Steel Company which roll these "H" section beams. The total capacity of the electrical equipment in this one room is nearly 85,000 hp., thus making it one of the largest industrial substations yet installed.

In the right center and extreme back part of the motor room are shown the reversing motors which drive the mill rolls of the roughing and intermediate 52-in. universal beam mills. Each of these mills has three pairs of rolls, all working simultaneously on various parts of the same beam section. The main horizontal and vertical rolls are driven by a 7000-hp. motor, and the horizontal edging rolls are driven by a 200-hp. motor, both of these reversing motors being supplied with power from a 6000-kw. flywheel motor-generator set.

Fig. 11—Main Motor Room, Carnegie Steel Company

Automatic control is provided, which permits a single operator to control the operation of the two motors, the three screwdown motors, and the several table conveyor and transfer motors. By means of a plug-in board, the ratio of the speeds of the two reversing roll motors is predetermined and selected for each pass, and the screwdown setting of each set of rolls is selected for each pass. During operation, the operator then advances a multi-point master switch one position after each pass, and the control functions automatically to adjust the ratio of roll motor speeds and to set each of the sets of rolls, ready for the next pass.

By this method of control, the operation of the mill is very greatly simplified, the number of operators is reduced, and the product is of uniform quality due to the same processing of succeeding pieces.

*Mill for Wide Flanged Beams.* Another large equipment of unusual interest was placed in operation at the Lackawanna Plant of the Bethlehem Steel Company. The mill to which the motors were applied is used to produce wide flange beams. It consists of three units; a 54-in. reversing blooming mill, a 48-in. intermediate mill, and a 48-in. finishing mill. The blooming mill, which is one of the two largest reversing blooming mills in this country, is driven by a single-unit d-c. reversing motor rated 7000 hp., continuously at 50 deg. cent. rise and 40/80 rev. per min. This motor is capable of exerting a maximum torque of 2,400,000 lb. at one ft. radius. Direct current is supplied from a flywheel, motor-generator consisting of a 5000-hp., 375 rev. per min., 6600-volt induction motor, a 50-ton flywheel and two 3000 kw., 750 volt generators which are operated in parallel.

Another noteworthy application at the Lackawanna Plant of the Bethlehem Steel Company is the change of the layout of the rail mill which is now being made. The 44-in. reversing blooming mill will have a driving motor rated 7000 hp. continuously, 50 deg. rise and 50/120 rev. per min. Blooms from this mill will go to a 35-in. reversing roughing mill which will be driven by a d-c. motor rated 5000 hp. continuously at 50 deg. cent. and 50/120 rev. per min. Power for these two reversing motors will be obtained from a single flywheel motor-generator consisting of a 7000-hp., 375 rev. per min., 6600-volt induction motor, two 3000 kw., 375-rev. per min., 750-volt generators operating in parallel to supply power to the 7000-hp. blooming mill motor, two 2200 kw., 450-volt generators operating in series to supply power to the 5000-hp. roughing mill motor and a 75-ton flywheel.

*Use of Synchronous Motors in Steel Mills.* The increase in the use of synchronous motors for main roll drives in the past year is noteworthy. The new applications for the year include a 5000-hp., 40 deg., 1000-rev. per min., 2200-volt motor used to drive a 19-in. continuous sheet bar mill at the Kokomo Plant, Indiana, of the Continental Steel Corporation. A motor of the same horsepower rating but at 240 rev. per min. will be used to drive a 51-in. piercing mill installed by the Standard Seamless Tube Co. of Economy, Pa. Other motors are applied to copper and brass rolling mills.

*Motor Rollers.* The first applications of rollers of the type in which the driving motor is inside of the roller and made integral with it were made in the past year. These applications include motor rollers on four different parts of a continuous sheet mill at the plant of the American Sheet & Tin Plate Co., Gary, Indiana. These rollers are of different capacities and speeds, depending upon their location in the table and vary from 5 to 35 cycles per sec. They are operated through motor-generator sets consisting of alternators and adjustable speed d-c. motors to give the necessary speed variation over the different parts of the table.

Another application of these rollers is that at the Lorain Plant of the National Tube Co. Applications here include motor rollers on a runout table for conveying the rounds from the furnace to the piercing mill. Others are used to feed the pipes to and from the threading machines, this installation being entirely automatic, and still others for conveying the tubes through the oiling machines. All of the rollers for the National Tube Co. are made of a special form to accommodate the round stock.

There are many advantages in the use of motor rollers over the geared or coupled type of drive, chief of these being simplicity of mounting with resultant simplicity and cheapening of the table supports, and economy in space and power, and extreme flexibility of operation.

### OIL INDUSTRY

Although electric power was slow to invade the field of oil production, rapid progress has been made during the last two years and now there are many fields using electrical power exclusively. A very good résumé of the operation of an electrically operated oil field is given in the *Electrical World* under date of February 4, 1928.

*Application of Electricity to Pipe Line Pumping.* Recently electric power has been used for pumping oil through pipe lines to replace the slow-speed plunger pumps driven by steam engines or occasionally a Diesel engine, on account of their very high first cost.

During the last two or three years pump manufacturers have made rapid strides in the design of centrifugal pumps suitable for this service and the engineers of the pipe line companies are beginning to realize the advantage of motor-driven centrifugal pumps for this work. Some of these advantages are low first cost, low maintenance, low attendance charges, quickness of installation, and reduced friction head due to steady even pressures. The low first cost (usually one-sixth to one-eighth of the steam station of the same capacity) is of considerable importance in selecting equipment, especially when the life of the field being served is of questionable duration and low fixed charges are prime factors in the total operating costs.

In the summer of 1927 the Illinois Pipe Line Company desired to increase the capacity of their main line across the State of Ohio, from 15,000 bbl. a day to 22,000 bbl. Rather than install additional pipe line capacity at great expense, this company put in booster stations using motor-driven centrifugal pumps at intermediate points between the steam stations. Ten five stage, 650-gal. per min., 1660-ft. head centrifugal pumps driven by 400-hp., 220-volts, three-phase, 60-cycles, 1800-rev. per min., synchronous motors with direct connected exciters were installed in five booster stations, two units per station. Only one pump is required to operate in each station, the second unit acting as a standby. See Figs. 12 and 13. Magnetic pushbutton starters of the auto-transformer type are used throughout, with pressure gages arranged to shut down the motors in case of low or excess pressures. The two pumps, motors, control and auxiliary equipment are mounted in a pump building 24 ft. by 34 ft. A fire wall is placed between the room containing the pump and the room containing the electrical equipment; the motor shaft passes through a stuffing box in the fire wall.

The sucess of these first installations has caused this company to purchase and install 27 additional units of the same kind to operate their new line running from Yates Pool to West Texas to Del Rio. Other companies have also realized the advantages of electric power for this service and have made similar installations so that this method of pumping is rapidly becoming the standard for pipe line service.

FIG. 12—SYNCHRONOUS MOTORS IN BOOSTER STATIONS

### ELECTRICAL WELDING

There was a marked advance in the application of electrical welding during the past year, both for the fabrication of electrical machines of all sizes and for the fabrication of structural beams and pieces necessary in the building industry.

FIG. 13—MOTOR-DRIVEN CENTRIFUGAL PUMP

The use of welded frames is rapidly becoming universal on account of the great saving in weight which can be accomplished by this method. Fig. 14 shows a welded frame for 100,000 kv-a. turbo generator and Fig. 15 shows a fabricated stator frame for one of the 40,000 kv-a. water-wheel generators for Conowingo.

*First Arc Welded Railway Bridge.* The first arc welded bridge of the through girder type is shown

nd behind the

This bridge spans the power canal passing through Chicopee Falls, which is approximately 50 ft. wide. Owing to the layout of the railroad facilities, however, the bridge is required to cross the canal at an acute angle of 72 deg. As a result the trusses are approximately 135 ft. long and the over-all length of the bridge is approximately 175 ft.

The outstanding feature of interest in the design of the bridge is the fact that the welded design requires 80 tons of steel, whereas the riveted design, prepared by the railroad engineers, required 120 tons of steel. Also the connecting material in the case of the welded bridge runs less than 5 per cent of the weight of the structure whereas in the case of the riveted design the weight of the connecting material is almost 30 per cent of the weight of the total structure.

FIG. 16—ARC WELDED RAILWAY BRIDGE

*Atomic-Hydrogen Arc Welding.* Development work on atomic-hydrogen arc welding was completed and a commercial equipment was produced for use on 60-cycle circuits.

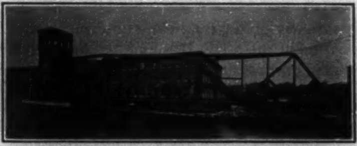

FIG. 17—COMPLETED ARC WELDED THROUGH TRUSS TYPE BRIDGE

With this method of arc welding, an alternating current is maintained between adjustable tungsten wire electrodes, Fig. 18, and hydrogen is fed to the arc around the electrodes. The hydrogen molecules are broken up into atoms by the intense heat and, in recombining outside of the arc and in contact with the work, heat is liberated far in excess of that obtainable by any gas flame alone. This heat is used to fuse the metals to be joined and, where additional metal is required, a filler rod may be fused into the work.

The hydrogen, being an active reducing agent, prevents the formation of oxides and hence produces a uniformly strong, ductile, and smooth weld. The metal being welded is not in the electric circuit and need not be grounded or insulated. The arc, constantly maintained, but broadly adjustable in size and in intensity, lends itself to a wide range of work.

A transformer furnishes the required voltage, and the current at the arc is controlled by an automatic reactor. In this process, high voltage and low currents are required in the arc, which is the reverse of the conditions in ordinary arc welding. The arc is struck at 300 volts; but while welding, the arc voltage is varied from 90 volts for light work to 60 for heavier, and the current correspondingly varies from 20 to 70 amperes.

By this means, homogeneous ductile welds can be made on very thin metals or on some metals and alloys hitherto considered unweldable.

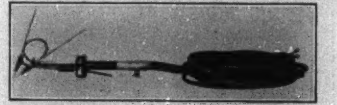

Fig. 18—Atomic Hydrogen Welding Torch

*Magnetically Controlled Arc Welding.* It is claimed by one manufacturer that the superimposing of a strong magnetic field on the arc flame, permits the arc to travel through variable magnetic fields without disturbance. This magnetic control appears to give the arc a gyratory motion and the controlled arc has been called an "electronic-tornado," the magnetic field apparently giving a swirling or gyratory motion to the electrons in the arc. It is claimed that welds made by this new process are more uniform in structure and ductility than those of ordinary arc welding.

Heretofore metal deposited by electric arc welding has partaken of the characteristics of cast steel. By this new process the metal deposited in the weld shows equal or even better physical characteristics than the metal of the plates joined by welding. This is said to be a result of the purifying effect of the electronic tornado.

An article in the January issue of the *Welding Engineer* indicates that a metallurgist who examined micrographs of welds made by this magnetically controlled process states that actually the weld is heat treated steel, and for that reason is entirely free from undesirable hardness and that the refining effect of this new welding process produces weld metal fully as good as that which can be obtained in rolled steel of the same general purity.

### CONTROL

Control has made many developments during the past several years and much was done during 1927. A great many individual devices could be cited indicating the improvements made. The following are given more or less to show the general trend of control. Generally, it should be pointed out that the evolution of dependable definite timing devices has limited the use of current limit and counter e. m. f. schemes of control. The general run of magnetic control is now of the definite time accelerating type.

The year 1927 saw a great deal of development and improvement in thermal overload relays for motor protection and protection for other machinery. The developments during the year are also noteworthy with respect to improvements in magnetic switches. Much has been learned with respect to the characteristics of different metals used as contact breaking and carrying points, also with respect to the advantages of multiple break per pole.

*Automatic Pump Control.* In the automatic control of a pump installation where the centrifugal pump is installed at a higher elevation than the sump, a vacuum pump is usually required for priming the centrifugal pump. The use of a pump valve to keep the pump filled with water so rarely gives satisfactory results in an automatic installation that this method of priming is not often recommended. The use of a sequence drum has made an improvement in automatic pump control. This sequence drum provides the automatic control to start the pump at high water level, stop the pump at low water level, and go through the priming process in starting. It repeats the priming cycle three times if necessary to prime the pump. If the pump is not primed after a third attempt, the sequence drum will lock out the control and a contact will be made on the drum energizing alarm circuit. In case the vacuum breaker switch remains closed, after the pump has primed, the main motor will not be disconnected from the line, but the sequence drum will stop on alarm contact, ringing alarm and lock out starting control, until repairs have been made. The sequence drum is, of course, motor-operated. See Fig. 19.

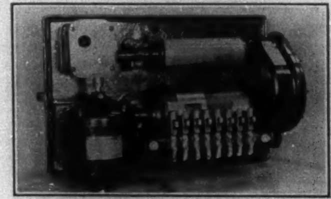

Fig. 19—Motor-Operated Sequence Drum

*High-Pressure Valves.* In connection with the motor operation of large valves in steam power plants and in the chemical industry, the trend is toward extremely high pressures, up to 3000 lb. per sq. in., and relatively high temperatures. This has imposed unusual requirements as to the positive and accurate seating of the valves. Strains and resultant deformations may result from the pressures and from expansion and contraction of parts due to temperature changes. Also, dissimilar metals are used such as monel stems and chrome steel valve bodies, which have unlike temperature coefficients of expansion. Therefore the standard motor control with a mechanical limit set for an accurate number of turns of the yoke nut would, under certain conditions, not close the valve tight, or under other conditions it might seat the valve before this mechanical limit was reached and thus damage the valve seat.

To meet these conditions, a torque-limit valve control has been developed. This control assures the seating of the valve at a definite predetermined seating pressure, or a fixed torque of the motor.

The controller is provided with a mechanical limit which operates while the valve is still at an appreciable distance from the seat. When this limit operates a torque device relay is cut into circuit and as the valve approaches the seat, the seating pressure builds up, increasing the current passing through the motor until it reaches a predetermined value, at which time the motor is disconnected, properly seating the valve.

The control system allows full torque on the motor up to the actual tight seating point of the valve, and this type of control should be used for closing all Globe type of valves, and for gate type of valves on pressures exceeding 450 lb. per sq. in. and on temperatures of 500 deg. cent. and above.

*High-Speed Printing Presses.* The development of high-speed presses for printing newspapers and the tendency toward the use of a-c. power has produced new problems in the control and drive.

In operating newspaper presses a two-motor drive consisting of a small motor and a large motor, is generally used. The small motor operates through a gear train and overtraveling clutch, and is used to start, inch, and thread the paper through the press, at a speed of approximately 1200 papers per hr. The large motor which is connected direct to the press, drives it during the regular printing operation. The slowest speed required is for registering, which is at a speed of about 9000 papers per hr.

Newspaper presses operating at a maximum speed of 36,000 to 40,000 papers per hr., using 2, 3, and 4 press units of 16-page capacity each, are easily controlled and operated over the entire speed range either by d-c. adjustable speed motors or a-c. slip-ring motors, as the a-c. motors can be satisfactorily operated at a reduced speed equal to 25 per cent of normal, which is necessary to obtain the proper take-off speed. However, on high-speed presses operating at 60,000 papers per hr., the reduction in speed, without special provision, required on the a-c. slip-ring motor is so great that it results in breakage of the paper web during the transition period when the main driving motor takes the load from the starting motor.

To obtain satisfactory results on high-speed presses driven by a-c. slip-ring motors, a special control equipment has been developed. The objective is to obtain the same take-off speed for registering the web and to obtain the same pull on the paper web during the transition period, accelerating to the same printing speed as is obtained by means of regulating resistance in the secondary of the main motor on slower speed presses. To accomplish this a torque relay is used in connection with the equipment, which controls the torque of the press through a torque switch during the transition period. As the main motor accelerates, this torque relay controls the main motor and interrupts the acceleration when a certain speed and torque is reached. If, during the transition period, the speed falls below a certain point, this torque relay will again close the torque switch, tending to accelerate. The slight variation in speed obtained at this point is not perceptible and not objectionable from the printing standpoint.

The controller is operated from a push button station and when the web has been properly registered, the main motor can accelerate the press by manipulation of the push button station to the proper printing speed.

To date, a-c. control and drive equipments have been designed and operated on high-speed presses consisting of one and two 16-page units. Operating three or more presses together may involve some difficulties in collecting the paper webs.

*Paper Machine Drives.* A control system has been developed for giving remote control of the paper speed on sectional paper drives.

Sectional paper drives are generally operated by individual motors which are driven from a common generator and the speed is controlled by varying the voltage of the generator. In order to obtain stable speed the generator is provided with a voltage regulator.

In the past the voltage of the generator and the speed of the drive has been controlled manually at the motor-generator set, and the problem resolved itself into voltage control of the generator from a remote point and still keeping the generator under control of the voltage regulator at all times.

To obtain these results the voltage regulator operating by means of the torque produced in a moving electromagnetic system is used. Movement of this torque mechanism commutates the generator field current directly through regulating resistances. The torque system is connected directly across the voltage to be regulated and any voltage changes cause a displacement in the moving element because the torque produced in that element operates in opposition to an elastic recall system.

In order to compensate the regulator to cause it to regulate at a different voltage, it is only necessary to change the resistance in series with the torque coil. A motor operated rheostat which simultaneously commutates the generator field and the torque resistance is used to effect the voltage change. Proper space resistance relations of the two circuits maintains the voltage regulator in operation at all times.

The voltage regulator and the motor operated rheostat is controlled by a push button located at the machine floor and the speed changes are accomplished without the attendance of an operator at the switch control.

*Furnace Top Control.* A variable cycle furnace top controller for use in connection with the McKee revolving top has been developed.

In the past it has been the practise to revolve the furnace top with the load deposited from the skip pocket before dumping into the big bell in accordance with a fixed cycle. Most commonly six loads have been dumped in succession at six different dumping points. With the newly developed controller, it is possible to vary the number of loads dumped into the different positions from four to nine. This change in cycle is being obtained by a manually operated position switch on the panel. This type of control insures better distribution in the material in the furnace as it is possible to vary the cycle depending upon the grade of material.

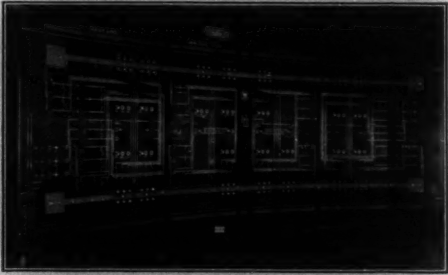

FIG. 20—SUPERVISORY CONTROL BOARD OF HOLLAND TUNNEL

*Holland Tunnel Supervisory Control.* The control equipment for the ventilation and operation of the Holland Tunnel connecting New York City with New Jersey has been designed to be handled by one man. This insures a maximum of safety with a minimum of operating force. The brains of this system is concentrated at the supervisory control board located on the top floor of the New York Administration Building. This board is built in the shape of an arc and composed of seven steel cabinets, as shown in Fig. 20, the cabinets being formed of sheets of ⅛-in. "stretcher-level" steel. At the rear and also within the cabinets are swinging steel doors, upon which are mounted the relays used on conjunction with the system.

The front of this board is a symbolic representation, both of a twin tube and the electrical circuit, including all feeders and motors. The board is divided by black vertical strips into five sections representing the four ventilation buildings and the mid-river sump. The names of the buildings are designated by name-plates shown near the top of the board. The two large trough-like castings running horizontally, one near the top and the other near the bottom of the control board, are symbolic of the north and south tubes respectively. The plateaus at the ends represent the plazas and the arrowheads indicate the directions of traffic.

Every oil circuit breaker control switch, motor speed switch, pump control switch, and their respective indicating lamps used in the tunnel equipment is duplicated on this board. By means of single direct-wire connections and the use of polarized type of relays, these various switches can control all the apparatus; likewise the lamps will indicate accordingly. The scheme of operation of this equipment is not at all like the standard supervisory control making use of the impulse method of using the automatic machine switching apparatus.

The control switches have a bar-like handle with the same finish as the miniature bus into which it is inserted. The position of this bar gives the operator a physical indication of the oil circuit breaker in addition to the indicating lamps. That is, when the control switch has been turned to close the breaker, the bar handle will be in line with the miniature bus. Likewise, when the switch has been turned to trip the oil circuit breaker, the handle of the switch will be left in a cross-wise position relative to the bus. When the control switch is turned to the closed position, its contacts impress a certain polarity over the single wire control to a receiving relay of the polarized type located in the ventilation building near the breaker. To trip same breaker the switch, when turned, will impress an opposite polarity on the receiving relay. The breaker lamp indication is brought back from the oil circuit breaker auxiliary switch to a receiving relay mounted on a swinging door in the rear of this control board; the same scheme of polarity that was used with the breaker control is employed also with the lamp indication.

At each breaker control switch, there is a green and white indicating lamp. The green lamp when illuminated, indicates that the breaker is closed. The white lamp has two degrees of brilliancy; the dim light indicates that the breaker has been tripped manually, while the bright light indicates that the breaker has been tripped automatically, due to some fault or failure.

The large lamp located on the raised part of the mimic tunnel, when illuminated, indicates what set of motors is feeding that particular section of the tunnel. The lamps on the upper raised section, above the trough indicates that the motors are being fed from the New York feeder, while the lamps on the lower raised station below the trough, indicates that the motors are being fed from the New Jersey feeder. Note that in order to insure continuity of service, each set of motors, consisting of a blower and exhaust, can be fed from either a New York bus or a New Jersey bus.

The large indicating lamp located in the trough of the mimic tunnel is connected to the carbon-monoxide recorder equipment. The illumination of this lamp indicates that there is more than two parts of carbon monoxide in 10,000 parts of air in the exhaust ducts. The small red lamp located in line with the carbon-monoxide lamp, when brightly illuminated, indicates that particular point in the tunnel from which the fire alarm has been sent in. The lights along the edge of the troughs close to the raised section, indicate what lighting cabinet is feeding the tunnel at that particular point.

On account of the method of ventilation used, the fans can be run on three different speeds. Consequently, the engineers selected motors of the wound rotor induction type so that speeds could be obtained by varying the resistance of the rotor. The three switches, grouped together in a vertical center line above the three large indicating lamps on the mimic tunnel, are for speed control. To select a particular speed, the key or handle must be inserted in the corresponding switch. In order to prevent the operator from forgetting to select a speed when he starts up any one of the fans in that particular section, an alarm will be sounded until the speed has been designated. The speed equipment consists of contactors with dashpots and a timing relay enclosed in a metal cabinet located near each motor in the ventilation building. The electric supply for the speed control is taken from a small distribution transformer located in the same housing as the breaker, which controls the main power circuit to the particular motor. As the motors can be fed from either New York or New Jersey bus, the small distribution transformers will be automatically fed from the respective bus.

As shown on the mimic tunnel, three fans feed each section of the ducts. One group of speed control switches is supplied for each section so that if three fans should be operating at the same time in the one section, all will be revolving at the same speed. A white indicating lamp is mounted directly above each speed switch; the lamp being illuminated above the corresponding switch of the particular speed selected.

On the lower half of the left-hand end of the control board are shown the three incoming feeders from power houses located in New Jersey, each feeder being 13,200 volt, three-phase, 60 cycles. On the upper half of the right-hand end of the board are shown in a similar manner the three incoming feeders, having the same characteristics as those from New Jersey, from power houses located in New York. In line with the miniature bus for these feeders, are white indicating lamps which are known as bus potential pilot lamps. These lights have also two degrees of brilliancy, when dim indicate that the feeder is alive; when bright indicate that due to some abnormal condition, the feeder has been opened. The lamp extinguished indicates that the bus is dead.

The incoming lines feed three-winding, air-blast, power transformers, which have secondary voltages of 2300 and 440 volts, these potentials being required for the motors. All oil circuit breakers are of the truck type design. The 13,200-volt incoming lines, all tie breakers, and the 2300-volt motor breakers are of the standard design, while the 440-volt motor breakers, on account of their number, are built in two tiers in order to save space.

All the protective relays used on the incoming feeders and motor circuits are located in the various ventilation buildings near the respective motors. The incoming lines are protected against short circuit. The three-winding power transformers have differential protection. The motors are protected by thermal overload relays which take care of excessive temperature rise due to overload. This same relay has a short circuit element which will act instantaneously if a short circuit occurs. To protect the motor during the starting and stopping period against failure of the speed control devices, and for protection, should the dampers within the air ducts be closed while the motors are running, a long time-delay undervoltage relay has been supplied.

From the above description of the supervisory control system and its control board, the supervisory operator knows and sees exactly how every piece of apparatus composing this gigantic network is performing. He can tell whether the incoming line breaker is still feeding the equipment, or whether it has tripped out automatically; whether or not the designated fans are running properly at the selected speed; whether the percentage of poisonous gas is dangerous in any section of the tunnel; if a fire alarm has been sent in, and what section is affected. The level of the water in the various sump chambers can be determined by certain lamp indications. Should any change be made in the position of any particular apparatus, due to some fault or failure, a bell alarm will be sounded and a bright light will indicate the location and character of the trouble.

## Miscellaneous Applications

*Brick and Clay Industry.* This industry is rather behind in the application of electrical power, the usual excuses being those of excessive dust, sulphur fumes, etc. These excuses are proved fallacious by installations in other industries. In one of the large Hudson River soft mud plants a complete electrified installation is now being built.

The superiority of electrical power over steam in clay plants is becoming universally acknowledged and practically all new plants are so equipped.

*Ceramic Industry.* Electrical energy is now recognized as an ideal fuel, particularly for ceramic manufacturers. It produces very clean heat, simplifies furnace construction and produces the highest percentage of No. 1 ware.

*Textile Industry.* Electric heating was adopted for the first time to the cloth singeing machines which are used in the finishing rooms of textile mills. The singeing was previously done by gas or oil heat.

Most of the singeing machines in operation at present are of the horizontal type with burners or hot contact plates mounted in horizontal rows so that the cloth is in a horizontal position in its travel over them. By the adoption of electric heating units, it was possible to arrange them vertically over each other in two rows, so that the cloth would be in a vertical position when traveling over them.

This arrangement not only makes available the close control of the temperature which is characteristic of electric heating, but it also reduces the floor space required for the machine.

*Bottle Making.* The *Electrician* of November 4, 1927 describes a new machine put out by European manufacturers which makes over 5000 large bottles an hour and smaller ones at a higher rate. The machine is driven by a 15-hp. adjustable speed motor and is equipped throughout with roller or ball bearings.

*Lighting.* The application of an electric flashing system and a lantern of new design displaced kerosene buoy lights on the New York Barge Canal.

Artificial light has been further used in the horticultural field.

There has been a large increase in the application of lighting of special kind in the medical field where cures can be effected by the equivalent of sun rays.

Also in the medical field should be mentioned the application of cathode rays and their effects in the production of vitamines in yeast and other foods. This research has been aided by the development in 1927 of cathode ray tubes for operating potentials of 900,000 volts. In 1926 the maximum operating potential was 400,000 volts. The higher potential has increased the velocity and range of the cathode ray discharge.

Under lighting should be mentioned the enormous increase in applications of neon tubes for commercial advertising. Also the development of a new type quartz neon gas-filled lamp which resembles a ball of reddish orange fire and has great fog penetrating possibilities.

A unique application of lighting is towards the elimination of certain moths and insects.

Flood lighting has been applied to harvesting operations and to the lighting of athletic fields for night sports.

*Synchronous Motors on Centrifugal Pumps.* The use of synchronous motors on centrifugal pumps is increasing as is noted by the demand for 1800-rev. per min. and even 3600-rev. per min. synchronous motors for this purpose.

*Oil Engine-Driven Alternators.* A 3750 kv-a., 124-rev. per min., 60-cycle alternator for direct connection to a Busch-Sulzer oil engine is being erected by Tucson Gas, Electric Light & Power Co.

*High-Voltage Transformers.* Three 500-kv-a., 750,000-volt transformers have been installed by the Ohio Insulator Co. of Barberton, Ohio. In this installation, the three transformers are connected in series and are thus capable of developing 2,250,000 volts above ground. This is said to be considerably higher than that developed by any other transformers in the world.

*Individual Wire Blocks.* The application of individual d-c. drive for wire blocks has rapidly increased. Between 350 and 400 blocks have now been installed in such a drive. The principal advantages are the flexibility of the individual drive since the wire block may be operated at any speed desired for the particular work at hand; smooth easy start which can be secured with direct current and the consequent control advantages in starting the wire through the die; the safety features which may be introduced in d-c. motors and control.

*Ward Leonard Control.* It is very interesting to note the number of new applications that have been found for this old principle. By the use of Ward Leonard control combined with field weakening on the motor, speed ranges as great as 20 and even 30 to 1 can be secured. With such a Ward Leonard system the control is very inexpensive and goes quite a long way toward paying for the extra expense of an individual generator. This type of drive has been used on galvanizing take-up frames in several instances.

*Tandem Drive for Strip Mill.* Several continuous strip mills have been installed in the last year with individual motor drive in each of the mills where the material is in several mills at the same time but without any loops in the steel. This can be accomplished by d-c. motors if the motors are carefully tested and calibrated to operate together with special provision in the fields for keeping the motors in correct speed relations, without developing a loop or stretching the steel.

*Anti-Friction Bearings.* The use of ball and roller bearings in motor applications has increased at a rapid rate. Many companies use this type of bearing exclusively. One company reports good success with the use of tapered roller bearings and the extension of their use to vertical motors, both alternating current and direct current, with very satisfactory results. The thrust capacity of the tapered roller bearing makes it ideal for many applications.

*Totally Enclosed Fan-Cooled Motors.* The totally enclosed, fan-cooled motor fills a demand for a moderately priced machine to successfully operate in the presence of dust or gas that has a deteriorating effect on insulation. These are generally of two types, those with external fans at both ends of the motor, which take in the outside cooling air at both ends and blow it towards the center, and those with fans at one end only, the cooling air being either drawn or blown across the motor from end to end. There is a constantly increasing demand for these fan-cooled enclosed motors and conditions indicate a considerably greater production this coming year.

*Texrope Drive.* This is a comparatively new development and was mentioned in a previous report of this committee. It is interesting to note that repeated tests show a transmission efficiency of 99 per cent for recommended maximum load. The large coefficient of friction allows the transmission of full power with a small tension on the loose side of the drive and successful operation with minimum bearing pressures.

# Mining Work

## ANNUAL REPORT OF THE COMMITTEE ON APPLICATION TO MINING WORK[*]

*To the Board of Directors:*

In reviewing recent progress made in the application of electrical power in mines, one is inclined to conclude that it has been effected by the general economic conditions prevailing in the mining industry. Over-production facilities in men and mines, labor problems, and freight rates are factors which are vitally influencing the prosperity and accomplishments of the business.

Conferences of mine managers and manufacturers of mining equipment, together with the meetings of engineering societies, indicate that the mechanization of mines is making great progress; in fact, definite conclusions have been reached that, under many conditions, mechanization pays. Considering the great investment required, and the new problems arising in the concentration of men, equipment, and supplies, creditable economies are being effected in the mechanical loading of coal where but an average tonnage is obtained from the equipment. Mine managers are realizing that the successful loading of coal is not solved by the purchase and installation of the machine, but that it involves many other operations, such as mining the coal, car dispatching, transportation, and mine planning. The question of cleaning the coal must also be included, since machine-loaded coal contains the impurities which, in hand loading, are left in the mine.

In 1926, about ten million tons of bituminous coal were loaded mechanically by 455 machines, this being an increase of approximately 60 per cent over 1925. While no complete reports are available at the present time concerning the number of machines in operation during 1927, certain information indicates that there will be a decided increase over those used in 1926. Due to the suspension of mining in Illinois and Indiana, the tonnage loaded in 1927 will not show much increase.

As the mechanization of mines continues, so does also the demand for equipment approved by the United States Bureau of Mines. This is due to the fact that much of the equipment required in mechanical loading and conveying machinery is used at the face workings where the maximum danger from gas and dust exists. The use of electrical equipment approved by the Bureau of Mines is becoming so general that there is in operation a bituminous coal mine with a daily output of 3500 tons, in which all of the underground electrical apparatus carries the permissible plate of the Bureau. Power for the motors in the mine is supplied by storage battery power trucks.

In some mines, mechanical loading means the use of several 125-hp. scraper hoist motors. A loading system of this type requires the transmission of power at 2200 volts. Proper protection is attained when using electricity at the above voltage, by the use of metallic armored cables placed in intake airways, and supported by a steel messenger wire. A cable crossing a track is taken underneath it in a conduit or concrete duct. Branch line taps are safeguarded with the usual protected oil switches.

The maintaining of a satisfactory d-c. voltage at the working face becomes more important each year. A 200-kw. portable rotary converter with its necessary accessories has been profitably used to attain such results. The transformers, switchboard, and control panels are mounted on trucks with the same gage as the mine tracks. A special frame structure is bolted to the converter making it possible to attach a truck to it. A movement of the entire station is contemplated every six months. Experience has shown that a complete move requires a period of eight hours.

An improved electric cap lamp consisting of a two-filament gas filled bulb and a bakelite head piece has been placed on the market. The new bulb produces more light, and the head piece, being an insulator, reduces the possibility of accident when worn in the vicinity of electrical conductors. When the main filament burns out, the auxiliary filament may be turned on, thereby enabling the miner to complete his day's work or come out of the mine. As the intensity of illumination in the mines is increased, greater safety may be expected, and no doubt an improvement in the efficiency of labor will follow.

Comprehensive dispatching systems are being placed in operation, their success depending upon a more general use of telephonic and automatic signal systems. In large mines, a system of this type is necessary to get the highest operating efficiency from the haulage system. Telephones are used to distribute the cars, and a signal system moves the trains over the main haulage roads. These systems relieve the mine foremen of considerable detail work, and give them more time for other important mine management problems.

The haulage costs in mines with a large output are being reduced by the introduction of larger mine cars and heavier locomotives. Main line locomotives equipped with three axles and weighing 35 tons are now being used in mines where two-axle locomotives were too small for economical operation. Locomotives of this type have an electropneumatic control, air brakes, and dynamic braking for handling loads on down grades.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

An increase in the motor capacity of large locomotives is being obtained by the use of forced ventilation, which is produced by a separate motor-driven blower mounted on the locomotive. The ventilation of the motors has been found to double their continuous rating. Notwithstanding the additional equipment necessary for ventilating the motors, the results obtained are so satisfactory that it has been adopted as standard practise by some manufacturers building three motor locomotives weighing 25 to 35 tons.

The largest mine locomotive ever built has been recently placed in service. It weighs 38 tons, has a 36-in. gage, and semi-elliptic leaf type springs with a three point equalization. Three 133-hp., 500-volt d-c. motors with forced ventilation will furnish the power. A semi-magnetic control arranged for series parallel operation of the motors in either direction constitutes the control equipment. The drawbar pull on level track at 33⅓ per cent adhesion will be 23,333 lb. at a speed of 7.4 mi. per hour.

Mechanical loading has concentrated and increased the service required from gathering locomotives to such an extent that heavier and slower speed locomotives are proving to be the best type. A reduction in the speed of gathering locomotives to 3½ mi. per hour makes it possible to do the same work with a consumption of 30 to 40 per cent less power.

The transportation of coal long distances by belt conveyors instead of locomotives is making progress. Mines in which the coal travels from the face to the tipple on conveyors are possibilities.

The world's largest electrically operated shovel will go into operation during this year in the open-pit mines of Illinois. It is equipped with a 15-cu. yd. dipper, and a boom 120 ft. long. Two 450-hp. motors will provide the power for hoisting, and two 150-hp. motors will do the swinging. A Ward Leonard control will be used, involving a motor generator set, the synchronous motor of which will have a capacity of 1700-kv-a. Shovels of this size will reduce the unit cost of the material handled, and make it possible to increase the ratio of overburden to coal in strip mining.

Where gaseous mines are being supplied with electrical power from large public utility plants over long transmission lines, installations are being made which will make it possible to operate the fans, and to hoist the men during periods when the normal supply of power has failed. An installation of this type consists of two fans, and a man hoist driven by a-c. motors, three-phase, 60 cycles, and 2200 volts. When an interruption of the power occurs, the above equipment is supplied with power at 40 cycles, and 1500 volts. Under these conditions, the control apparatus will function properly, and the motors will operate at two-thirds speed, which is sufficient to keep the mine clear from gas and to hoist the men. The emergency power is produced by a gasoline-engine-driven, 200-kv-a. generator capable of being started by a push-button in case of a power interruption.

A notable electrification program of a large copper mining company has just been completed. The complete electrification of its 28 mines with a connected motor load of about 65,000 hp. shows that electrical power is an important factor in the copper industry. Engineers have overcome many difficulties in the installation and maintenance of electrical apparatus in copper mines, where the action of copper sulphate is so harmful.

In another open-pit copper property, there are 23 electrically-operated shovels in service. This year the entire steam haulage system consisting of 52 steam locomotives will be replaced by 37 trolley locomotives each weighing 75 tons.

In hard rock ore mines, as distinguished from coal mines and other soft ore mines, experiments are being conducted on the electrical equipment required by loaders, slushers, and other machinery. Much progress is being made in the adaptation of motors to this exceptionally severe service.

Automatic controls for mine substations, fans, pumping plants, and air compressors are being continually developed and placed in operation. At the present time there are about 200 automatic pumping stations in operation in the anthracite coal field, representing an annual saving in labor cost of approximately $500,000. The automatic stopping and starting of air compressors has been developed and several are in successful operation.

A rather unique application of electricity in the mining industry consists in using it for heating the bathing water for those employees who work on holidays or during periods when most of the regular force is idle. In one instance, a steam plant is necessary to heat the water for the normal force of 600 men, while during idle days, immersion heating units in a tank provide sufficient hot water for the reduced force of 25 men.

It is becoming more noticeable each year that the managers of the mines are giving more attention to the maintenance and care of the electrical equipment, resulting in a decreased maintenance cost and a better operating efficiency. The mine electrician in charge of the electrical equipment is given more authority and is directed by the electrical engineer in all technical questions. Frequent inspections of the mine by the engineer and the electrician, together with a good operating organization materially reduce the number of equipment failures, so disastrous to good production.

# Marine Work

## ANNUAL REPORT OF COMMITTEE ON APPLICATIONS TO MARINE WORK*

*To the Board of Directors*:

The activities of the Committee on Applications to Marine Work this year were devoted chiefly to the dissemination of the Marine Standards (A. I. E. E. Standard No. 45), cooperation with the N. F. P. A. (Committee on Fire Detection and Alarm), cooperation with the American Marine Standards Committee on specifications for water tight receptacles, and the expenditure of further efforts to induce the U. S. Steamboat Inspection Service to recognize and properly classify the electrical engineer on shipboard.

A. I. E. E. Standards No. 45 were issued in June 1927. The committee this year made a special effort to distribute the Standards to all departments of the marine industry likely to be interested and as a result of this campaign 750 copies were sold.

The Standards are recognized and accepted by the various marine classification and insurance societies, naval architects and marine engineers, and are incorporated as one of the regulating provisions in their specifications. A. I. E. E. Standards No. 45 are therefore a recognized success and will serve to standardize the electrical installations on shipboard and to stimulate the use and proper care of electrical machinery in the marine field.

The Conference Committee on Fire Detection and Alarm requested our cooperation in connection with recommendations which it was preparing for the Steamboat Inspection Service, of fire alarm and fire detecting systems. In compliance with this request, our committee reviewed its proposed recommendations in detail and subsequently held a joint meeting with its representatives, at which all points of difference were discussed.

The committee also cooperated with the special committee on water tight receptacles appointed by the American Marine Standards Committee of the Bureau of Simplified Practise, to draw up specifications for water tight receptacles for shipboard service.

Considerable time was spent in connection with the proposition of inducing the U. S. Steamboat Inspection Service to make provision in its regulations for the proper rating and classification of the electrical engineer on shipboard. To this end, our committee prepared its report containing a statement of the status of the present electrical personnel, reasons for higher and proper rating and recognition of the electrical engineer on board ship, together with a suggested list of ratings and grades for the electrical personnel of the various classes of ships. These recommendations were made in such manner as to permit licenses in the different electrical grades being taken out by those of the present steam and Diesel classified engineers who qualified.

This report was presented by our subcommittee on personnel at the annual meeting of the U. S. Steamboat Inspection Service in Washington in January. Although final action was deferred by the Steamboat Inspection Service at its annual meeting, it decided to take our recommendation under consideration in the regular routine of its body and prepared plans to circularize the marine operators for the purpose of soliciting their opinions in the matter of classifying electrical personnel. It is felt that favorable action will be taken by the Steamboat Inspection Service and its regulations modified in the course of time. Our subcommittee on personnel is keeping in close touch with the situation.

In addition to the above chief items considered by the committee this year, the question of revision of present specifications was taken under advisement and arrangements made to keep the specifications up to date automatically by considering and acting upon all proposed changes as they are presented. In this way the time and effort required to get out the revised issue when necessary will be considerably minimized.

The outstanding electrical developments in the marine field during the past year are as follows:

1. The construction of five 3000-ship hp. turbine-electric drive U. S. Coast Guard Cutters.
2. The placing in service of the S. S. *California*, an 18,000-ship hp. twin-screw turbine-electric drive passenger ship for the Panama Pacific Steamship Line. A sister ship to the *California* is now under construction.
3. The conversion by the U. S. Shipping Board of three of their largest cargo vessels (*Courageous*, *Defiance*, and *Triumph*) to Diesel electric drive. These vessels will have machinery suitable for 4000-ship hp. normal and 4500-ship hp. maximum continuous.

Besides the above chief developments there has been a number of smaller craft equipped with electric propulsion. The application of electrical equipment to ships is continuing at an increasing rate and the future looks hopeful indeed.

With the passage of the Jones-White bill and its approval by the President, the American Merchant Marine has received its first real encouragement since the World War period. This bill contains several provisions which will undoubtedly stimulate the American marine industry. We can anticipate rapid developments in which electricity will play a very important rôle.

# Electric Transportation

## ANNUAL REPORT OF COMMITTEE ON TRANSPORTATION[*]

*To the Board of Directors:*

The application of electricity to transportation proceeded during 1927 at a healthy rate, and new developments in apparatus and equipment continued, several interesting applications being introduced during the year.

### Steam Railroad Electrification

Although no new electrification projects of major importance were completed during the year of 1927, two extensions were opened which had as their particular aim the further simplification of electric operation already existing, *viz.*, the Bay Ridge extension of the Long Island Railroad permits electrically-operated freight trains from the New York, New Haven & Hartford Railroad to pass over the Hell Gate Bridge Route to the tidewater freight terminal at Bay Ridge, Long Island; the Chicago, Milwaukee, St. Paul & Pacific Railroad has electrified its passenger terminal in Seattle, Washington, together with its line from Black River Junction over which trains had previously been handled by steam power.

Of the incompleted projects: the Pennsylvania Railroad will place in service shortly its suburban electrification from Broad Street Station, Philadelphia, to Wilmington, Del. and West Chester, Pa. The Great Northern Railway is proceeding with the extension of electric operation from Cascade Tunnel to Wenatchee, Washington. The New York Central Railroad is electrifying its west side freight yards in New York City. The New York, Westchester & Boston Railway is continuing its line to Port Chester, N. Y. The Detroit, Toledo & Ironton Railroad is working on the extension of its existing electrification from Flat Rock on to Petersburg, Mich.

The principal new project getting under way at the present time is the electrification of the suburban lines of the Reading Company around Philadelphia, Pa. It has been announced also that the Boston, Revere Beach & Lynn Railroad is planning to electrify its line.

Of electrifications placed in service during the year of 1926, one of the most interesting, the Chicago Terminal electrification of the Illinois Central Railroad, reports a marked increase in traffic and revenue for the first year of operation.[1]

*Long Island Railroad.* The Bay Ridge extension of the Long Island Railroad has been electrified with the 11,000 volt overhead catenary, single-phase, 25-cycle system for freight operation. This line joins the Bay Ridge freight terminal of the Long Island Railroad with the New York Connecting Railroad's Hell Gate Bridge Route to the New York, New Haven and Hartford Railroad at Port Morris, N. Y. The route is 20 miles in length.

Power is transmitted over a 22,000-volt, three-wire system with 11,000 volts between trolley and ground, and is received from the New Haven Railroad distribution system; in emergency it can be obtained from one 5000-kw. variable ratio frequency changer at the Long Island's East New York substation. This frequency changer is normally used as a synchronous condenser for power factor correction. No. 4/0 copper feeder wires are connected to the trolleys through auto-transformers at six balancer substations, four of which are on the Long Island and two on the New York Connecting Railroad.

The catenary system is non-ferrous with a single 4/0 bronze contact wire, copper auxiliary wire and high-strength bronze messenger wire. Inclined catenary is used in general on curves. The supports consist largely of rolled structural "H" beams. Rails are bonded with two No. 1 copper, 37-strand flame-welded bonds per joint.

The seven double-unit, gear-drive locomotives built for switching service have a wheel arrangement of 0–6–0 + 0–6–0, and weigh 158 tons each. The six motors on each complete locomotive are rated at 235 volts and operate with forced ventilation. The maximum starting tractive effort is 100,000 lb. and can be obtained up to 7½ mi. per hour. The maximum operating speed is 25 mi. per hour. Through traffic is handled by New Haven locomotives.

In addition to the Bay Ridge a-c. electrification, the Long Island Railroad is adding to its d-c. operation to the extent of 75 mi. of freight tracks and sidings, which will allow electric operation of all freight service within the electrified portion of the railroad. The work is 50 per cent completed and is to be completed by October 1st, 1928. A special "T" section third-rail of high conductivity is being used for all sidings and yard tracks.

*Chicago, Milwaukee, St. Paul & Pacific Railroad.* The western terminal of the Chicago, Milwaukee, St. Paul & Pacific are Seattle and Tacoma, Washington. Electric service ran into Tacoma, and service to Seattle had been handled by steam from Black River Junction. During the year of 1927, the line, 10 mi. of double track from the junction into Seattle, was electrified. Power is furnished from the earlier electrification through the overhead distribution system, and no new substations were constructed. This electrification is 3000-volt,

---

[*] COMMITTEE ON TRANSPORTATION:

J. V. B. Duer, Chairman.

Reinier Beeuwkes,
E. R. Hill,
W. K. Howe,
D. C. Jackson,
John Murphy,
W. S. Murray,
W. B. Potter,
N. W. Storer,
H. M. Vandersluis,
Richard H. Wheeler,
Sidney Withington.

[1] *First Year of Electric Operation in Chicago*, by W. M. Vandersluis, A. I. E. E. Quarterly Trans., Vol. 47, 1928, No. 1, p. 217.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

d-c., with an overhead catenary system having a double contact wire.

*Pennsylvania Railroad.* The Pennsylvania Railroad is completing the electrification of its suburban service from Philadelphia, Pa., to Wilmington, Del., on its main line to Washington, and to West Chester, Pa., on the Wawa Branch. This project was outlined in last year's report. Overhead catenary is used, energized with 11,000-volt, 25-cycle, single-phase current.

*Great Northern Railway.* The project of the Great Northern Railway to electrify its line between Wenatchee and Skykomish, Wash., is proceeding rapidly. Grade and curvature realinements are being made, and the new Cascade Tunnel from Berne to Scenic, (7.79 mi. long) is more than 65 per cent completed. Electric operation, which now extends from Skykomish through the old Cascade Tunnel, is to be extended through the new tunnel and on to Wenatchee before the end of 1928. The project will operate on 11,000-volt, single-phase, 25-cycle power, using motor generator locomotives with d-c. traction motors.

Orders have been placed for locomotives similar to those which are now in operation; that is, two additional type 2-6 + 6-2 and two additional type 2-8-2 + 2-8-2 locomotives, having continuous ratings of 3000 hp. and 3660 hp. respectively.

*New York Central Railroad.* The New York Central Railroad is proceeding with the electrification of its west side yards in New York City. The overhead trolley system at 600 volts d-c. is to be used as far down town as 60th Street. Below this the motive power will be self-contained power units.

*New York, Westchester & Boston Railway.* The New York, Westchester & Boston Railway is completing the extension of its Port Chester, N. Y., line as far as Rye, N. Y. Multiple unit suburban service is operated on 11,000-volt, 25-cycle, single-phase power.

*Detroit, Toledo & Ironton Railway.* The Detroit, Toledo & Ironton Railway is proceeding with the electrification of 26 mi. of line from Flat Rock to Petersburg, Mich. This will be an extension of the existing 11,000-volt, 25-cycle, single-phase electrified line described in last year's report, which runs from Fordson to Flat Rock, Mich.

*Reading Company.* The Reading Company is planning extensive improvements in its Philadelphia facilities, and expects to electrify 85 mi. of track with a 11,000-volt, 25-cycle, single-phase system.

Power will be furnished to this electrification over 22,000-volt feeders by a three-wire system with 11,000 volts between the overhead catenary and ground. The eventual program calls for transmission between substations at 66,000 volts.

The initial project comprises multiple unit service from the Reading Terminal in Philadelphia to Chestnut Hill, to Lansdale on the Bethlehem Branch and to Hatboro.

*Boston, Revere Beach & Lynn Railroad.* The Boston, Revere Beach & Lynn Railroad, a narrow gage line running out of Boston, Mass., plans to electrify a route of 15 mi. It is proposed to use a 600-volt overhead catenary system for multiple unit operation.

### CITY AND SUBURBAN RAILWAYS

On electric street railways increased acceleration is being obtained by the use of light weight cars and more powerful motors with the latest design of control, thus tending to relieve congestion on city streets.

Trial installations of the new type of drive mentioned in last year's report have been put in service in a number of instances. This is the automotive type propeller-shaft drive by which unsprung weight is greatly reduced, with a corresponding reduction in noise and maintenance. Improved installations have been made in reduction gear drive with entirely spring-suspended motors having a flexible driving joint.

### MARINE PROPULSION

The largest turbine-electric passenger ship, *California*, was launched October 1st, 1927. The displacement is 30,250 tons. Power is supplied to the propellers by two synchronous induction type motors each with a maximum continuous rating of 8500 ship hp. at 120 rev. per min.

The installation of Diesel-electric drive has been extended during the year to include three new lightships for the Department of Commerce as well as coast guard cutters, large double-ended ferry boats, a packet boat, and cargo boats.

### BUS TRANSPORTATION

Gas-electric drive for motor buses and motor coaches is increasingly popular. Experiments have been made on electric transmission for taxicabs.

### RECENT DEVELOPMENTS

*Diesel Electric Locomotives.* The past year brought forth a novel arrangement of the Diesel engine prime mover with electric drive:

In electrification of its west side yards in New York City the New York Central Railroad has decided to use an overhead contact wire within the city limits only as far down town as 60th Street. Below this point it is desirable to employ a self-propelled unit. The locomotive chosen for this service, therefore, operates on third rail or trolley at 600 volts d-c., or can be propelled by power from a self-contained 300-hp. Diesel engine-driven generator, augmented for peak requirements by a storage battery. When load requirement is for less than 300 hp. the current from this battery is replaced by the generator.

*Gasoline-Electric Rail Cars.* During the year of 1927, approximately 150 gasoline-electric motor rail cars were ordered by the railroads of the United States. One 300 hp. oil-electric car was placed in service.

*Trolley-Storage Battery Locomotive.* Two electric locomotives furnished with power from a storage battery and also from an overhead trolley wire are in service for yard switching service on the Chicago, North Shore & Milwaukee Railroad. When the locomotive is receiving current from the trolley the battery is charged by a motor-generator set.

*High-Speed A-c. Circuit Breakers.* Although oil circuit breakers with rapid operating characteristics have been available for several years in a-c. switching, one of the most interesting developments of the past year has been the construction of an air circuit breaker for operating on 11,000-volt a-c. circuits and having speed characteristics similar to d-c. installations This type, as well as oil circuit breakers operating on the same principle, is to be used by the Pennsylvania Railroad on its extension of electrified suburban service around Philadelphia.

*Overhead Catenary.* The construction of overhead catenary on the Great Northern Railway electrification from Skykomish to Wenatchee, Wash., is an application of the formula proposed by O. M. Jorstad[2] for inclined catenary.

*Supervisory Control.* All four transformer substations on the Philadelphia to West Chester electrification of the Pennsylvania Railroad are to be controlled from the Wawa signal tower by supervisory control. The synchronous visual type is being installed.

Another interesting installation of supervisory control is the West Hempstead substation of the Long Island Railroad, now under construction, at which three 1000-kw. mercury arc rectifiers are controlled from Mineola substation two miles away. The rectifiers can be started by the supervisory system in approximately 20 sec.

*Train Communication.* Radio communication between locomotive and caboose and between train and station has been the subject of considerable experiment. An installation of this type is in service on the New York Central Railroad.

*Mercury Arc Rectifiers.* The use of the mercury arc rectifiers in electric railway substations is still limited to a few installations. A summary of the operating experience of one railroad with this equipment is contained in a paper entitled *Operation and Performance of Mercury Arc Rectifiers on the Chicago, North Shore & Milwaukee Railroad Company.* This paper was presented by Caesar Antoniono at the Regional Meeting[3] in Chicago, Ill., November 28-30, 1927.

## TECHNICAL PAPERS

The committee has obtained for presentation at the 1928 Summer Convention a group of interesting papers. They are as follows:

*High-Speed Circuit Breakers,* by J. W. McNairy, General Electric Company.

*The High-Speed Circuit Breaker in Service on the Illinois Central Railroad,* by W. P. Monroe and R. M. Allen, Illinois Central Railroad.

*Arrangement of Feeders and Equipment for Electrified Railways,* by R. B. Morton, Gibbs & Hill, New York, N. Y.

*Operating Experience with High-Speed Oil Circuit Breakers,* by B. F. Bardo, New York, New Haven & Hartford Railroad.

*High-Speed Circuit Breakers for Railway Electrification Work,* by H. M. Wilcox, Westinghouse Elec. & Mfg. Co.

*Protection of Electric Locomotives and Cars to Operate with High-Speed Circuit Breakers,* by E. H. Brown, Pennsylvania Railroad Co.

# Electric Welding

## ANNUAL REPORT OF THE COMMITTEE ON ELECTRIC WELDING*

*To the Board of Directors:*

During the past year, marked progress has been made in the application of electric welding to an increasing number of industrial uses including welding of pipe, pipe lines, structures, and cracking stills for gasoline production. A few outstanding applications are mentioned by way of example in the following paragraphs.

One of the largest welding jobs completed during the year was the Mokelumne River Project, a pipe line supplying water to Oakland and other Bay Cities near San Francisco. This line is 90 mi. long. The pipe is 66 in. in diameter and its thickness varies from 3/8 in. to 5/8 in. depending on the water pressure in the particular section of pipe. This job is completed and is, so far as known, the largest single job of welding which has ever been undertaken.

This pipe was so large that it was necessary to join two plates in order to get the required diameter, one joint being made on each side of the pipe. These were welded by the automatic carbon-arc welding process. After each section of the pipe was welded, it was tested by hydraulic pressure at a fiber stress of about 23,000 lb. per sq. in., and while under this pressure, heavy sledges were dropped from a 4-ft. height on each side of the joint, the sledges being one foot apart. This gave a shock test to the joint at the time when it was subjected to the maximum hydraulic pressure.

The contract price on this job of arc welding was twelve million dollars. The best figure offered for the same pipe riveted was fifteen million dollars.

During the year, 45 mi. of 7-in. oil pipe line was electrically arc welded in Louisiana. The pipe was made in the ordinary way and the ends of the pipe were welded. The chief advantage of this method is that the finished pipe line is free from the leakage that sometimes occurs at joints made by threaded couplings in the old way.

This pipe was welded at $1.25 per joint contract price. According to the people who did the welding, the actual cost was 58 cents per joint. The best proposition for welding this pipe by any other method than the metallic arc was $2.75 per joint.

During the year, a number of cracking stills for the production of gasoline from crude oil were welded by the A. O. Smith Corporation. They have been put into service for carrying pressure as high as 1000 lb. to the square inch and a temperature as high as 900 deg. fahr. This is work which can be done only by the welding process. The results cannot be accomplished at all by the older riveting process.

Four papers on electric arc welding were presented at the Winter Convention of the Institute. One of these papers by J. B. Green[1] of the Fusion Welding Corporation dealt with the influence of the covering of the electrode on the characteristics of the arc. During its presentation slow-motion pictures of the arc taken with infra-red light were shown. These disclosed how the metal goes across the arc from the electrode to the work.

The paper by P. Alexander[2] of the Research Department of the General Electric Company at Lynn, Mass., dealt with the influence of the surrounding atmosphere on the arc.

The paper by A. M. Candy[3] of the Westinghouse Electric & Manufacturing Company described a five-story building recently erected by welding, and a paper by A. P. Wood[4] of the General Electric Company described what is being done at Schenectady in the way of welding electric machines of all descriptions.

Since that time, a bridge has been erected by welding by the Westinghouse Company at their plant at Chicopee Falls. This bridge has 80 tons of structural steel in its construction and would have required 120 tons if it had been erected by the riveting method in the regular way.

Early in 1928 three prizes offered by the Lincoln Electric Company for the best papers on electric arc welding through the American Society of Mechanical Engineers were awarded by a committee of seven judges representing the Engineering Societies and the Bureau of Standards.

The first prize of $10,000 was awarded to J. W. Owens of the Newport News Shipbuilding & Dry Dock Company, for a paper on "Electric Arc Welding in Ship Construction."

The second prize of $5000 was awarded to Professor H. Dustin of Brussels, Belgium, for a paper covering the method of calculating the strength of welding, giving data not heretofore available.

The third prize of $2500 was awarded to H. E. Rossell of the Philadelphia Navy Yard on the use of electric arc welding in the construction of bulkheads.

The American Welding Society has had committees on structural-steel welding and on pressure-vessel welding at work during the year and substantial progress has been made in the work of the committees, although no final report has been issued.

# Iron and Steel

## ANNUAL REPORT OF COMMITTEE ON APPLICATIONS TO IRON AND STEEL*

*To the Board of Directors:*

Your committee is pleased to present the following statement covering the progress of development in applications in the Iron and Steel Industry during the year ending July 31, 1928.

Constantly during this period the iron and steel industry has added to its general electrical equipment. These general additions have been towards modernizing of existing installations quite as much as anything, and all effort is directed steadily towards reduction in production costs by addition of improved machinery.

The tendency to increase blast furnace equipment is not present and this may be said to be true generally of the fundamental processes of smelting iron ore, in coverting iron into steel or in rolling the steel into the primary shapes. Such electrical additions as have been made in the foregoing are in the nature of changes of older equipment to modern.

The principal interest during the current term has been in the finished product mills which we shall term the secondary mills.

Predominant in this regard are installations in strip mills and in cold rolling, these electrical installations being modern and recording definite advance in the production of hot strip steel and in cold rolled strip.

Close regulation of the mill drive is required and to give this, motors and control have been developed and installed. Micrometric adjustment of the rolls has been obtained through motors and control specially designed for the purpose. The reeling of the strip steel has been accomplished automatically by mechanical tools, electrically driven and controlled. This accomplishment marks a definite advance in the production of perfect strip steel.

Steady improvement in detail of motors and control for such service is shown in the apparatus installed, and this is marked rather than any positively new product of our industry.

Throughout the term your committee has kept in touch with the proceedings and personnel of the Association of Iron and Steel Electrical Engineers. It has been our purpose to help the Association as we may and its proceedings again are referred to the Institute as the most complete record available of developments electrically in the Iron and Steel Industry.

In conclusion, your committee commends the plan of keeping continually in touch with the Association of Iron and Steel Electrical Engineers, giving it service wherever possible and bringing to the Institute its reports and findings, with suitable recognition. Your committee just concluding its services takes this means of acknowledging and expressing its appreciation of the assistance rendered by these reports for the current term, as well as by the constant contact with representatives of the Association.

# High-Speed Circuit Breakers

J. W. McNAIRY*
Associate, A. I. E. E.

*Synopsis.—High-speed circuit breakers have been successfully applied to d-c. railway systems for a number of years, but designs suitable for application on 12,000-volt single-phase systems have not been available until recently.*

*A description of an air circuit breaker design suitable for 12,000-volt applications and having a speed of operation comparable with the d-c. type has been included.*

*The method of applying the magnetic type of mechanism previously used for d-c. breakers to the a-c. type breaker has been described. The theory of the operation of the saturated transformer type of trip circuit used for this purpose has been given.*

*Typical oscillograms of short circuit tests showing the high speed of operation on a-c. circuits are included.*

*The method of obtaining selective operation in connection with railway feeder circuits has also been outlined.*

*The use of this type of breaker on a 12,000-volt single-phase system makes possible the same degree of protection and selective operation as is now being realized on d-c. systems.*

## I. Introduction

HIGH-SPEED circuit breakers were first applied on d-c. railway systems for the protection of commutating apparatus against the effects of short circuits or flashover. Later development led to their application to all of the power circuits of this type of system. A paper describing the principal features of a complete breaker installation of this type on the d-c. terminal electrification of the Illinois Central R. R., Chicago, was presented at the June 20, 1926 meeting of the A. I. E. E.† Reference was made at that time to the development work being carried on in connection with a-c. applications.

The higher voltages of the trolley network of the usual a-c. system make high speed operation of circuit breakers more difficult and progress has, therefore, not been as rapid as with the d-c. type. Some applications to railway feeders of a-c. breakers designed to operate considerably faster than the usual oil breaker, have been made in the past, but speeds approaching that of the d-c. breaker have only recently been attained.

Both oil and air break types having a speed of operation comparable with the d-c. type have recently been developed and commercial designs suitable for a-c. voltages up to 12,000 volts are now available.

The application of an air circuit breaker to this type of service marks the first application of breakers of the air type to moderately high a-c. voltages.

## II. Advantages of High-Speed Operation on A-c. Railway Circuits

Short circuits are necessarily more frequent on railway systems than on other types of power distribution networks, because of the nature of the service. High-speed operation of the protecting breakers for single-phase a-c. systems reduces the effects of short circuit stresses on transformer and generator windings and limits burning of insulators, conductors, or parts of motive equipment from arcs resulting from these short circuits, in the same manner as on d-c. applications. Breakers of this type are frequently effective in preventing the burning off of trolley wires in case of an insulator, arc-over thereby minimizing delays in service from this source.

One of the most important problems in connection with a-c. railway electrifications is that of inductive interference with adjacent communication and signal circuits under short circuit conditions. The low impedance of the grounded track return circuit results in a maximum current in case of failures of the trolley circuit, and the ground current is, therefore, usually limited only by the impedance of these metallic conductors. The railway circuit differs in this respect from the usual power circuits where there is no ground metallic return circuit. Induced voltages in adjacent low voltage circuits are therefore, on the average, higher and appear more frequently than in regions where ordinary power distribution networks are located.

It is expected that the application of high speed breakers to the a-c. railway system will greatly reduce this interference by reducing to a minimum the duration of induced voltages in the parallel circuits. The reduction in the duration of the induced voltage minimizes the duty on protective devices in the communication circuits and it is expected that the false operation of relays, bells, and other devices, resulting from this induced voltage will be eliminated to a great extent. This is, perhaps, one of the greatest benefits to be derived from the application of this type of circuit breaker to the a-c. railway feeder.

## III. Speed of Operation

The total time required for the operation of the usual a-c. circuit breaker may be divided as follows: 1, time required for relay operation, 2, time required for the separation of contacts, and 3, time required for extinguishing the arc.

In some forms of breakers, particularly those the subject of this paper, the relays have been eliminated, the circuit breaker being operated directly by the short circuit current.

The speed of operation of the mechanism is more or

*Railway Equipment Engg. Dept., General Electric Co., Erie, Pa.

†A. I. E. E. Trans., Vol. XLV, 1926, p. 962.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

less definitely fixed by the mechanics of the device and separation of the contacts occurs at a definite time after the trip point is exceeded.

For a-c. applications, the preferred breaker is one which opens the circuit at the normal zero point of the current wave, thereby avoiding undesirable voltage transients. Since separation of the contacts may occur at any instantaneous current value depending upon the magnitude of the short circuit current and the displacement of this current wave, the arc extinguishing system should be so proportioned that the current will not be forced down too rapidly before a normal zero point is reached.

This is usually not difficult since at zero current no energy is delivered to the arc and it is most easily extinguished at this point. It is possible, however, to design high speed breakers having too powerful a blowout or current rupturing system so that when the first short circuit current loop approaches a cycle in duration, and the contacts open when the line current is near the peak of the wave, the circuit may be opened too rapidly and undesirable transient voltages may result.

It is sometimes assumed that most failures on a single-phase 12,000-volt system occur at the peak of the voltage wave and, therefore, the usual short circuit is symmetrical with a duration of a normal half cycle for the first current loop. A great many short circuits, however, are produced mechanically, the conductors coming together so that the short circuit is established at any point on the voltage wave. Records obtained during experimental investigations using contacts in both air and oil for applying short circuits at 12,000 volts show transients having all degrees of displacement of the current wave.

The duration of the first loop of current is, therefore, frequently less than one-half of a normal cycle. The magnitude of the current of such a first loop is not a fair indication of the severity of the short circuit and the breaker does not receive full tripping current or current through the blow-out system until after the second current loop is reached.

The design of a breaker to limit all short circuits to a single loop of current, therefore, is difficult and if successful, the relatively powerful current rupturing system might reduce the current at a dangerous rate when the first loop approaches a cycle in duration.

It therefore appears that the most logical design of an a-c. breaker is one capable of opening heavy short circuits at the first zero after a current loop having a duration of one-half a normal cycle or longer.

## IV. OIL VS. AIR TYPE BREAKERS

One method of obtaining high speed operation is greatly to increase the mechanical speed of the conventional type of oil breaker so that sufficient arc length is obtained in the specified time for the interruption. This means the exertion of relatively great operating forces either by powerful springs or solenoids with a corresponding increase in the mechanical difficulties in starting or stopping the mechanism.

One of the most effective means of rapidly increasing the arc length is by means of the magnetic blow-out. By properly directing the forces exerted on an arc stream drawn between contacts of a circuit breaker by the fields of the blow-out coils, the arc can be lengthened at almost any desired rate. The contacts of the breaker therefore need only be separated sufficiently to stand the voltage as the circuit is opened by the collapse of the arc stream. By applying the magnetic blow-out to an oil breaker, the necessary contact separation at the instant the circuit is interrupted can be greatly reduced and a mechanism moving at moderate speeds can be utilized.

The speed of operation and rupturing capacity of experimental switches of this type have met expectations.

Elimination of oil, however, is always desirable where possible. This is particularly true for railway applications.

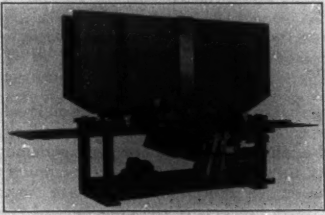

FIG. 1—12,000-VOLT, 1500-AMPERE A-C. AIR HIGH-SPEED CIRCUIT BREAKER WITHOUT OUT-DOOR HOUSING

The feeder network of important sections of electrified railway systems where continuity of power supply is imperative, requires a relatively large number of breakers for proper sectionalizing. On four-track systems of this type, the 12,000-volt breakers may average as high as two per mile and the maintenance of such a large number is obviously an important item in the operating expense.

Exposure of current carrying conductors of the railway network to the wear and tear of current collectors, in addition to conditions common to all aerial conductors results in frequent short circuits. The majority of these failures are to ground, which in railway circuits means a line to line short, the current being limited by circuit reactance only. Railway circuit breakers are therefore frequently called upon to open heavy short circuits.

The effect of repeated interruptions on oil circuit breakers is well known. If a given circuit breaker is called upon to open a circuit repeatedly without attention, the oil deteriorates to such an extent as to endanger the reliability of the breaker. Repeated short circuits are most likely to occur during bad weather conditions when filtration or changing of the oil is most difficult, particularly in outdoor installations. The air breaker is therefore much to be preferred for this type of service, assuming that it is the equivalent of the oil breaker in all other respects.

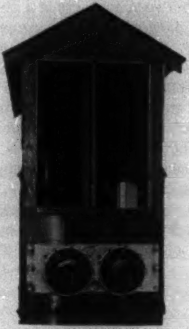

FIG. 2A—HIGH-SPEED AIR CIRCUIT BREAKER IN OUT-DOOR HOUSE WITH ONE END REMOVED TO SHOW LOCATION OF CIRCUIT BREAKER. ALSO SHOWS LOCATION OF HIGH-VOLTAGE TERMINALS

The d-c. air break circuit breaker has demonstrated its ability to withstand repeated short circuits without deterioration or objectionable damage to contacts. A-c. air break breakers of the same general type have, during experimental investigations, withstood 20 or more maximum short circuits repeated at two minute intervals without requiring attention or without deterioration of the current rupturing ability, and are on a par with the d-c. type in this respect.

FIG. 2B—12,000-VOLT, 1500-AMPERE HIGH-SPEED AIR CIRCUIT BREAKER COMPLETE WITH OUT-DOOR PROTECTIVE HOUSING OPENING 24,000 AMPERES AT 14,000 VOLTS. OSCILLOGRAM OF TEST SHOWN ON FIG. 6

On the other hand there is this to be said against the air circuit breaker:

1. The air breaker proper is not suitable for outdoor mounting and a protective housing is necessary. An air breaker complete with self-contained housing suitable for outdoor installations, is shown on Fig. 2. Fig. 2B was taken by leaving the photographic plate exposed while the breaker was opening a 24,000-ampere, 12,000-volt short circuit, the oscillogram of which is shown in Fig. 6.

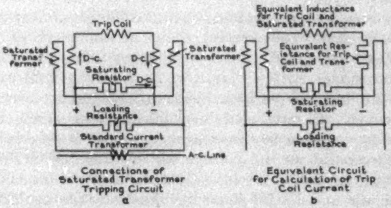
2. The operation of the circuit breaker on heavy short circuits makes somewhat more noise than the oil type.

3. The application of the air breaker is at present limited to the moderately high a-c. voltages.

Both types of breakers will, therefore, undoubtedly find a field of application on a-c. railway feeder circuits.

## V. MAGNETIC OPERATING MECHANISM

Practically all d-c. high speed breakers are of the magnetic tripping type, most designs making use of a flux shifting principle, where the flux is shifted from a holding armature to a magnetic by-pass circuit to release the breaker. The principle of operation of the flux shifting type is well known and has been described repeatedly in publications.* Briefly, it consists of a holding magnet energized by a d-c. coil across the poles of which a holding armature is bridged. Between the poles a tripping coil is introduced in such a way that when a current of proper polarity is applied the flux is shifted instantaneously from the armature to the core of the tripping coil, thereby releasing the breaker. This type of mechanism, when tripped under short circuit conditions by the line current, provides practically instantaneous release by eliminating tripping relays, a very effective arrangement when maximum speed is desired. This mechanism has been successfully applied to both oil and air type 12,000-volt a-c. breakers.



Connections of Saturated Transformer Tripping Circuit
a

Equivalent Circuit for Calculation of Trip Coil Current
b

FIG. 3—CONNECTIONS OF THE TRIPPING CIRCUIT FOR THE MAGNETIC TYPE OF A-C. HIGH-SPEED CIRCUIT BREAKER

Some means of providing a unidirectional current in the tripping coil of this type of mechanism is essential for applications on a-c. circuits. The saturated current transformer type of trip circuit was adopted for this purpose, Fig. 3. The tripping circuit is usually designed for current of 5 amperes so that standard current transformers can be used in the main power circuit.

---

*Tritle, U. S. Reissue Patent 15,441.

"New Type of High Speed Circuit Breaker," by J. F. Tritle, *G. E. Review*, Vol. XXIII, p. 286.

The operation of this trip circuit perhaps may be better understood by first considering the phenomena responsible for the so-called "starting current" when voltage of proper polarity is suddenly applied to a transformer, the core of which is magnetized by residual flux. The "starting current" for the transformer is the result of lowered reactance because of over-saturation of the core, the available range in flux in one direction having been reduced because of the initial residual flux.

The transformers used in the tripping circuit are of normal current transformer design. When there is no alternating current through the windings, the flux in the cores of these transformers is maintained near the saturation point by direct current through one of the windings of each transformer, this current being the same as that used for the holding coil of the circuit breaker.

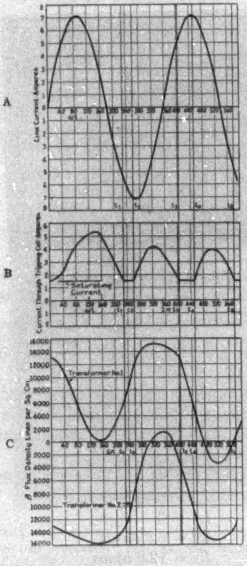


FIG. 4—CALCULATED CURRENT AND FLUX CURVES FOR SATURATED TRIPPING TRANSFORMERS USED IN CONNECTION WITH THE MAGNETIC TYPE OF MECHANISM OF THE A-C. HIGH-SPEED CIRCUIT BREAKERS

The connections are such that when current of given direction is passed through the primary winding of both transformers, such as during the first half cycle of an a-c. short circuit, it exerts a m. m. f. to increase the flux in the core of one transformer and decrease the flux of the other transformer simultaneously.

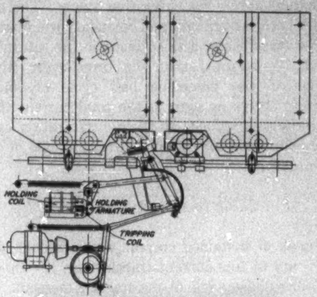

FIG. 5—OPERATING MECHANISM OF THE AIR BREAK 12,000-VOLT A-C. HIGH-SPEED CIRCUIT BREAKER

Since the cores of both transformers are initially saturated in opposite directions, the decreasing flux in one transformer generates a secondary voltage whereas the transformer in which the flux is increasing generates only a slight secondary voltage because of saturation in the core. The secondary voltages of the two transformers are connected in opposition around the tripping coil circuit and the resultant unbalanced voltage circulates current around the circuit formed by the trip coil, transformers, and resistors as shown by the current curve of Fig. 4b.

No matter what the direction of the primary current, one transformer will be active on the first half cycle, the polarities being such that the current impulse through the trip coil is always in the same direction. The phenomenon is transient and the unidirectional current is not maintained under steady state conditions.

This arrangement does not provide a steady overload trip point so that standard types of overcurrent relays are usually provided for this purpose. The high speed trip functions only in case of short circuit or heavy overload which results in a suddenly increasing line current.

Any of the usual types of relay protective systems may be used in conjunction with the high speed trip.

In an endeavor to provide a more complete explanation of the operation of these saturated transformers, the following analysis is offered:

The performance of the transformers is affected by magnetic hysteresis in the iron core. The following analysis is intended mainly as an indication of the factors affecting the performance of these transformers and hysteresis effects have therefore been ignored for the sake of simplicity. The following assumptions were also made for the same reason.

1. The transformer which is active for a given direction of primary current is assumed to hold its ratio from the instant the flux is started down, that is, the exciting current is assumed to be negligible.

2. The inductance of the transformer which is inactive because of saturation has been assumed to be constant above the saturation value. The current through both the primary and secondary windings of the inactive transformer acts to increase the saturation.

3. It is assumed that the transformer which is inactive on the preceding half cycle becomes immediately active as soon as the total current through the windings is reduced to the d-c. saturation value.

The expression for the line current in case of an a-c. short circuit is

$$I = I_M \sin(\omega t - \gamma) + I_M \sin \gamma \, \epsilon^{-\frac{t}{T}} \tag{1}$$

where

$I_M$ = peak of sustained current wave, through secondary of line current transformer, $t$ = time

$\gamma$ = time phase angle of the starting moment

$\epsilon$ = 2.718

The following symbols are employed.

$L_1$ = total inductance of trip coil circuit (saturated transformers and tripping coil)

$R_1$ = total resistance of trip coil circuit

$L_2$ = total inductance of loading circuit, Fig. 3

$R_2$ = total resistance of loading circuit, Fig. 3

$I$ = total current in secondary of line current transformer

$i_1$ = current through trip coil

$i_2$ = current through loading circuit

$\omega$ = $2\pi f$

$t$ = time in seconds

$T$ = time constant of main power circuit.

The equivalent circuit for the period during which a current impulse is passing through the tripping coil is shown by Fig. 3B.

The current through the tripping coil of the circuit breaker is determined as follows:

One to one ratio; saturated transformers are considered. The fundamental differential equation for the circuit is

$$R_1 i_1 + L_1 \frac{d i_1}{d t} = R_2 i_2 + L_2 \frac{d i_2}{d t} \tag{2}$$

also

$$I = i_1 + i_2 \tag{3}$$

$$\frac{d I}{d t} = \frac{d i_1}{d t} + \frac{d i_2}{d t} \tag{4}$$

substituting (1) in (2) and eliminating $i_2$ terms

$$(R_1 + R_2) i_1 + (L_1 + L_2) \frac{d i_1}{d t} = I_m \Big[ R_2 \sin(\omega t - \gamma) + R_2 \sin \gamma \, e^{-\frac{t}{T}} + L_2 \, \omega \cos(\omega t - \gamma) + \frac{L_2}{T} \sin \gamma \, e^{-\frac{t}{T}} \Big] \tag{5}$$

which is integrated for $i_1$

$$i_1 = I_M \Bigg[ \left( \frac{R_2(R_1+R_2) + \omega^2 L_2(L_1+L_2)}{(R_1 + R_2)^2 + (L_1 + L_2)^2 \omega^2} \right) \sin(\omega t - \gamma) + \left( \frac{\omega L_2 (R_1 + R_2) - R_2 \, \omega (L_1 + L_2)}{(R_1 + R_2) + (L_1 + L_2)^2 \omega^2} \right) \cos(\omega t - \gamma) + \left( \frac{(R_2 T + L_2) \sin \gamma}{T(R_1 + R_2) - (L_1 + L_2)} \right) e^{-\frac{t}{T}} + C e^{-\left(\frac{R_1 + R_2}{L_1 + L_2}\right) t} \Bigg] \tag{6}$$

The above relation holds only during the period when one transformer is active and the other inactive.

The magnetic trip circuit is sufficiently responsive to trip on instantaneous current values, the armature being released if the current through the trip coil exceeds the setting during the peak of an a-c. wave. The breaker is therefore released on the first current impulse which exceeds the trip point and the determination of the first tripping impulse is most important in connection with breaker performance.

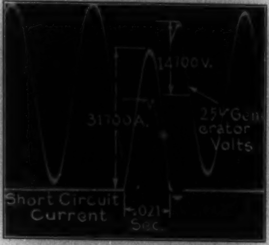

FIG. 6—OSCILLOGRAM OF "OCO" SHORT CIRCUIT TEST AT 14,000 VOLTS, 24,000 AMPERES, R. M. S. ON 12,000-VOLT AIR CIRCUIT BREAKER

The current through the trip coil of the circuit breaker for a symmetrical short circuit namely with $\gamma = 0$ has been calculated for a typical case using equation (6) as follows:

The constants of the circuits involved are as follows:

$L_1$ = 0.11 henrys
$L_2$ = 0
$R_1$ = 5.6 ohms
$R_2$ = 12.0 ohms
$T$ = 0.00625
$I_M$ = 7.1 amperes

Referring to Fig. 3a the resistance of the saturating resistor is made the same as the total resistance of tripping coil and transformer secondary windings and the steady direct current supplied to this circuit for saturating the transformers divides equally between the two parallel paths.

The resultant d-c. voltage drop produced by this current in the parallel paths is equal and opposite around the circuit through which the tripping current circulates and therefore does not enter into the determination of the tripping current with the exception that the current value obtained from equation (**6**) is superimposed on the d-c. saturating current as shown by Fig. 4b.

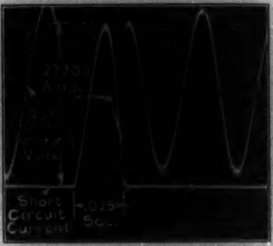

Fig. 7—Oscillogram of "OCO" Short Circuit Test at 12,000 Volts, 22,000 Amperes R. M. S. on 12,000-Volt Air Circuit Breaker

The integration constant $C$ is therefore determined by the initial conditions $t = 0$ $i_1 = 0$ and the expression $i_1$ for the first loop of current (Fig. 4b) is found to be

$$i_1 = I_M\,[.348 \sin \omega t - .342 \cos \omega t + .342\, e^{-160t}] \qquad (7)$$

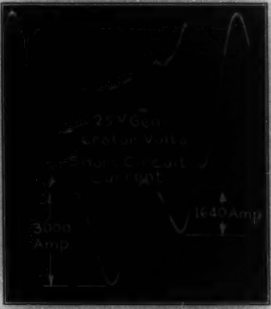

Fig. 8—Oscillogram of 12,000-Volt, 2700-Ampere R. M. S Short Circuit Test on Air High-Speed Circuit Breaker

The voltage can be found by differentiating (**7**) for $\dfrac{d\,i_1}{d\,t}$ and substituting this and (**7**) in

$$E = i_1 R + L_1 \frac{d\,i_1}{d\,t}$$

for the case under consideration.

$$E = I_M\,[7.858 \sin \omega t + 4.105 \cos \omega t - 4.105\, e^{-160t}] \qquad (8)$$

The flux of the active transformer is determined from

$$E = 10^{-8}\, I_m\, N\, A\, \frac{d\,\Phi}{d\,t}$$

$$= [7.858 \sin \omega t + 4.105 \cos \omega t - 4.105\, e^{-160t}] \qquad (9)$$

Where $N$ = number of turns on transformer secondary
$A$ = area of core sq. cm.

$$\Phi = \frac{10^8\, I_M}{N\,A}\,[\,.0262 \sin \omega t - .0502 \cos \omega t + .0257\, e^{-160t} + C] \qquad (10)$$

the initial flux is maintained at 13,000 lines per sq. cm. by the saturating direct current, therefore for

$$T = 0 \quad \Phi_0 = 13{,}000 = \frac{10^8\, I_M}{N\,A}\,[-\,.0502 + .0257 + C] \qquad (11)$$

and

$$C = -\,.0245$$

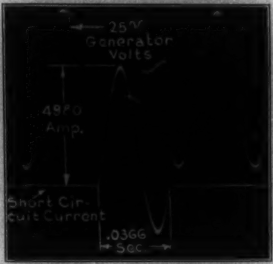

Fig. 9—Oscillogram of a 3700 Ampere R. M. S. 12,000-Volt Short Circuit Test on an Air Break Circuit Breaker

The flux curve calculated from (**10**) is shown by Fig. 4c.

It will be noted that at the time $t_1$ the current through the windings of the inactive transformer is reduced to the d-c. saturating current value, as the line current continues to increase during the second one-half cycle and a voltage is induced in the secondary winding of this transformer. From the flux curve of Fig. 4c, however, it will be seen that the flux of the previously active transformer has not yet returned to the saturation value and therefore there is a period from $t_1$ to $t_2$ where both transformers are active and present full transformer reactance to the flow of current and the total line current therefore flows through resistance $R_2$, (ignoring the exciting current for the transformers).

The flux change in both transformers for the period $t_1 - t_2$ is therefore determined by the voltage across the loading resistor $R_2$, Fig. 3a.

$$V = 10^{-8}\, I_M\, R_2\, N\, A\, \frac{d\,\Phi}{d\,t} = I_M \sin \omega t$$

$$\Phi = \frac{12 \times 10^8}{N\,A}\,[-\cos \omega t]$$

The corresponding flux curves for the period $t_1$ to $t_2$ until the flux of transformer No. 1 again reaches the saturation point, is shown on 4c. After saturation is reached, in the case of No. 1 transformer, a second current impulse is passed through the trip coil circuit by No. 2 transformer, the method of determination being the same as for the first impulse. At the conclusion of the second impulse, $t_3$, the flux of the second transformer is further from the saturation value than was the flux of No. 1 transformer at the end of the first loop and the line current again passes through $R_2$ until saturation is reached, the period from $t_3$ to $t_4$ being correspondingly greater than the period from $t_1$ to $t_2$.

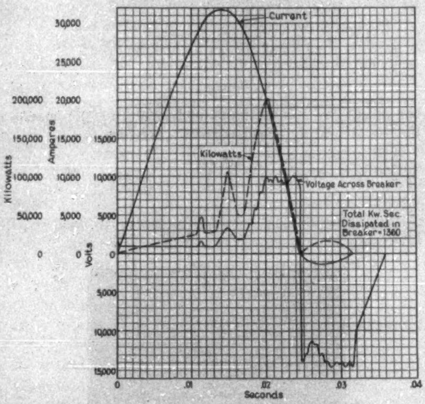

FIG. 10—CURVE TAKEN FROM OSCILLOGRAM FIG. 6, SHOWING KILOWATTS DISSIPATED IN THE ARC CHUTE OF AIR CIRCUIT BREAKER DURING A SHORT CIRCUIT TEST AT 14,000 VOLTS

In this manner the process is repeated, the period in which both transformers are active growing longer with each succeeding half cycle until a stable condition is reached where the flux is increasing through one transformer and decreasing through the other transformer for the full one-half cycle. When this occurs the sustained condition has been reached and no further current impulses are supplied to the trip coil so long as the line current is not increased. The full line current under steady state conditions passes through the resistance $R_2$.

The trip current supplied by this tripping circuit is approximately proportional to the increase in line current. Typical oscillograms showing the tripping current are shown on Fig. 11. The oscillograms of Fig. 11 were taken when applying an overload to the circuit which was previously carrying a steady load. The saturating current in this case was passed through an independent winding on the saturated transformers.

After the steady state condition is reached, should the line current be suddenly increased again, the saturation point is reached on one transformer as soon as the line current exceeds the steady state value and further current impulses are supplied through the tripping coil circuit.

## VI. DESCRIPTION OF THE AIR BREAK CIRCUIT BREAKER

Photographs of a 12,000-volt 1500-ampere single-phase air break circuit breaker are shown on Figs. 1 and 2. A drawing of the principal parts of the mechanism is shown in Fig. 5. The armature, which is held in the closed position by a holding coil and released by a wire wound trip coil inserted between the poles of the holding magnet, is shown connected to the main high voltage contact arm through insulated pull rods.

The high voltage contact arms are operated entirely through suitable insulating pull rods, the mechanism being grounded. The circuit breaker as a whole consists of two sets of contacts and arc chutes which are connected in series, the moving contact arms being connected together by a suitable bus so that they form in effect a bridging contact similar to that used in oil circuit breakers.

There are two sets of springs, the main springs operating directly on the armature for opening at high speed while the contact pressure is exerted by a second set attached to the pull rods at the bottom of the arm.

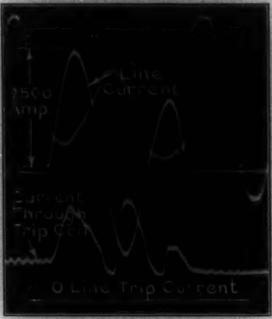

FIG. 11—TYPICAL OSCILLOGRAMS SHOWING CURRENT OBTAINED WITH SATURATED TRANSFORMER TRIPPING CIRCUIT FOR MAGNETIC TYPE OF HIGH-SPEED A-C. CIRCUIT BREAKER

This mechanism is inherently trip free, the operation being as follows:

Resetting is accomplished by means of a motor-operated cam. The first movement of the cam operates the lever attached to the pull rods at the bottom of the contact arms rotating these arms about the top bumper as a fulcrum. The holding armature is pulled to the closed position by the main pull rods attached between the center of the contact arms and the bell cranks on the armature shaft. This armature is latched as the peak of the cam is reached without reducing the gap between contacts. Further movement of the cam allows the bottom springs to rotate the contact arm to the closed position around the top pull rods as a center.

The bottom of the arms when opening on short circuits, is held approximately stationary when opening by the weight of parts attached to the bottom. In the event the breaker is closed on a short circuit the mechanism therefore operates the contact at full speed regardless of the fact that the rollers have not yet left the cam surface.

The high voltage circuit through the breaker is very direct, entering on one side through series blow-out coils, one end of which is connected to a stationary contact. The circuit is completed through the moving contact and arm and another set of series blow-out coils from which the connection is made to the second contact mechanism, a duplicate of the first.

When the contacts separate under short circuit conditions, the arc is drawn on the arcing horns and detached blow-out coils are cut in successively as the arc travels along these horns. The general arrangement of the blow-out coils, arc suppressor plates, arcing horns, etc., is the same as that used on standard designs of 3000-volt d-c. breakers with the exception that a greater number of blow-out coils is used and the arc chutes are designed to permit a considerably longer arc.

A new feature which is introduced in this breaker consists of high resistance arcing horns made from a special material and designed to absorb a considerable voltage as the arc is forced along them under the action of blow-out coils. These arcing horns are effective in reducing the energy in the arc stream and in reducing the flame and noise of the breaker when opening under short circuit conditions.

Some typical oscillograms obtained during short circuit tests, including tests at 14,000 volts single phase, 25 cycle are shown in Figs. 6 to 9 included. The curves on Fig. 10 were plotted to show the current, voltage, and power relations during a short circuit test of 14,000 volts. It is interesting to note that the energy is liberated in the arc chute at a maximum rate of 200,000 kw.

The speed of operation of the mechanism taken with a mechanical speed recorder is shown by the curve on Fig. 12. It will be noted that total tip gap of more than 6 in. (two contacts in series) is reached in slightly more than the time required for a normal ½ cycle (25 cycle) after the trip point is exceeded.

## VII. Current Rupturing Tests on Air Breaker

This breaker has successfully opened a current of 24,000 amperes r. m. s. at 14,000 volts repeatedly. A series of 20 OCO tests at 12,000 volts, 22,000 amperes, r. m. s. was made at two-minute intervals without examination or attention of any kind to the circuit breaker. A single contact and arc chute of this type of breaker, equivalent to one-half the standard 12,000-volt breaker has opened a maximum current of 41,000 amperes r. m. s. at 7000 volts repeatedly, both the tests at 14,000 and 7000 volts being the maximum available at the time the tests were conducted.

## VIII. Selective Operation of the High Speed A-C. Breaker

Selective operation of high speed a-c. breakers applied to railway feeders is essential. The high-speed feeder breakers should isolate defective feeder sections between substations without disturbing power flow to adjacent interconnected sections under all short circuit conditions.

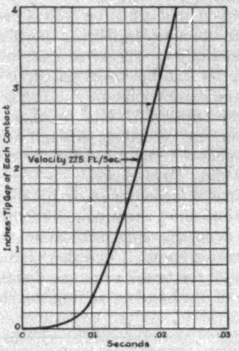

Fig. 12—Mechanical Speed of 12,000-Volt Air High-Speed Circuit Breaker

The connections shown in Fig. 13 are utilized for obtaining selective operation where the unidirectional current impulse type of trip is used. Advantage is taken of the unidirectional trip circuit in a differential connection. The tripping circuits of all breakers are connected to a common bus in such a way that the trip current circulating through any trip coil must return either through the trip coils of parallel breakers or the saturating resistor indicated on the diagram. When the current is increased simultaneously through all breakers feeding the feeders in a given direction from the substation, the tripping current for all of these breakers must pass through the saturating resistor shown on the diagram, since equal voltages are generated by the trip circuits of each breaker. The current required for tripping all of the circuit breakers under this condition is much higher than when the current is increased through one breaker only. By selecting a proper value for the saturating resistor the current necessary for operation with a simultaneous current increase through all breakers can be made higher than the exchange current over the trolleys between substations in case of internal short circuit in one substation.

If the current is suddenly increased in one breaker only, by a short circuit on one feeder, tripping current is supplied to the breaker supplying the faulty feeder, this current returning through the coils of the remaining breakers and assisting to hold them closed. The tripping current for the breaker involved is considerably less than when all breakers carry current because of the lower impedance of the return circuit for the tripping current.

A simplified diagram showing breakers located in a typical feeder network has been shown in Fig. 14.

The operation of the breakers under typical short circuit conditions with connections as shown in Fig. 13 is as follows:

1. *Feeder Short Circuits.*

In the event of a short circuit on a feeder between substations, the breaker supplying this feeder carries a current considerably in excess of that of the parallel breakers since the parallel breakers carry the exchange current between substations only. Tripping current is supplied to the trip coil of this breaker, operating it, some of this current returning through the trip coils of the parallel breakers in reverse direction for tripping and assisting in holding them closed.

In the event of a feeder short circuit directly in front of one substation, all of the breakers in the distant substation carry equal currents until after the breaker in the near substation opens. The short circuit current is removed from all the breakers at the distant station by the operation of the breaker feeding the short directly, except the distant breaker feeding the faulty trolley. The current through this breaker is suddenly increased because of the removal of the heavy short circuit current from the high voltage transmission line and this breaker is operated, clearing the remaining short circuit.

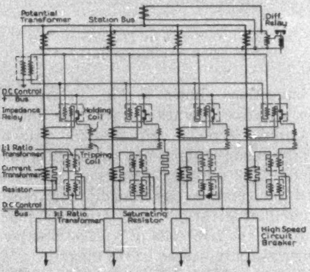

FIG. 13—DIFFERENTIAL CIRCUIT FOR SELECTIVE OPERATION OF FOUR MAGNETIC TYPE HIGH-SPEED CIRCUIT BREAKERS APPLIED TO A 12,000-VOLT TROLLEY FEEDER NETWORK

2. *Substation Bus Short Circuit.*

In the event a short circuit occurs on the bus at a given substation, all breakers interconnecting the two substations carry equal exchange currents. These breakers are, therefore, not operated by the high speed trip and the bus is isolated by the operation of a standard type of differential relay which opens all of the breakers connected to this bus. The feeders between substations are fed from the distant station and are not deenergized.

Standard Oil Circuit Breaker
Substation Bus
High Speed Feeder Breakers
12000 Volt Trolley Feeders

FIG. 14—SIMPLIFIED DIAGRAM OF A TYPICAL HIGH-SPEED BREAKER INSTALLATION ON A 12,000-VOLT RAILWAY FEEDER NETWORK

3. In case a short circuit occurs in the stepdown transformer or in the high tension line, the feeder breakers between the faulty substation and adjacent substation carry equal exchange currents and therefore do not receive a sufficiently high tripping current to operate. The faulty transformer or high voltage line is disconnected from the bus by the operation of a standard differential relay around the transformer or reverse power relays in case of a high voltage line short, both of which operate a circuit breaker on the low voltage side of the transformer.

## CONCLUSION

The development of both air break and oil break 12,000-volt a-c. high-speed circuit breakers having a speed of operation comparable with the d-c. type makes possible the same degree of selectivity and protection on a-c. electrified systems as has been obtained for a number of years on equivalent d-c. systems.

It is expected that this type of breaker will be particularly beneficial in minimizing inductive interference in signal and communication circuits.

# High-Speed Circuit Breakers for Railway Electrification

## From the Design Point of View

BY H. M. WILCOX[1]

Member, A. I. E. E.

FROM the point of view of switching service, circuit breakers as a whole may be divided roughly into general classifications dependent on the time required to isolate portions of the circuit under conditions of fault or to clear the circuit under any predetermined condition. Of these, the conventional normal-speed breaker constitutes by far the largest class in general use.

For d-c. switching service, this class is generally of the carbon-break type often applied in machine circuits with relatively high normal current loads requiring breakers of large current-carrying capacity with heavy moving elements. These breakers may be expected to interrupt a short circuit in from 0.07 to 0.10 sec. from the start of rise of short circuit current, although they are often used with a time-delay element intentionally placed in the control circuit to increase this time up to a full second or more. Where quicker action is desirable, particularly with breakers of lower current-carrying capacity, the contacts may be made trip-free from the closing mechanism and with a sensitive overload tripping device the time may be reduced to from 0.04 to 0.06 sec. The general form of the breaker, however, is not materially different in these two time classifications.

For a-c. switching service, the normal-speed oil circuit breaker is used over practically the entire range of service voltages. When actuated by a normal-speed relay, this breaker requires from 0.10 to 0.25 sec. after the occurrence of a fault to trip the breaker and interrupt the circuit. As in the case of the d-c. breaker, however, it is often used with a time-delay element in the control circuit extending the total time up to as much as three or four seconds. Where switching is mainly on the low side of the transformers the normal loads involved may require breakers of high current-carrying capacity with heavy moving elements, and for great concentrations of power the current rupturing requirements may be relatively high, calling for substantial sturdy construction of the contact details. When switching at higher voltages, the current loads become proportionately less, making lighter contacts feasible, and various forms of high speed contacts are used in which contact is maintained between arcing tips in the breaker until the main moving element has completed a considerable portion of its opening movement. The arcing tips are then snapped open at a high rate of speed independent of the speed of the main moving element, thus materially decreasing the duration of arcing. High-speed relaying is also resorted to where it becomes desirable to diminish the time between the occurrence of a fault and the drawing of an arc at the breaker contacts. In all of these forms, however, the breaker structures differ only in details and they may all be included in the same general classification.

During the last few years, the rapid advance in railway electrification work, particularly in the application of automatic features, has resulted in the development of a new class of breakers for this service known as high-speed circuit breakers. Developed largely for special protective purposes, these breakers perform a somewhat different function from that of breakers in other service for both of the two great classes of railway applications, d-c. and a-c. electrification projects. In time classification, high-speed breakers should function to interrupt a d-c. circuit in 0.02 sec. or less after the occurrence of a fault, and one cycle or less for a 25-cycle a-c. circuit.

In d-c. railway service, the synchronous converter operating at from 600 to 1500 volts occupies a commanding position as a medium for converting alternating current from the secondaries of transformers into direct current supplying feeder circuits for trolley or third rail service. This machine lends itself readily to automatic control without the necessity of an attendant, but is susceptible to flashing with considerable consequent damage to the commutating apparatus under short circuit conditions. To obviate this difficulty, the d-c. high-speed breaker has been developed to the point of interrupting a circuit before short circuit current can rise to its full value, and of so limiting the destructive period of duration of a short circuit as to preclude the possibility of flashing on the commutator. Fig. 1 shows a high-speed circuit breaker designed for 1500-volt d-c. railway service.

From the design point of view, certain characteristics must be incorporated in this breaker to meet the requirements for high-speed protection in d-c. circuits. The operating voltage for the majority of railway applications is 600, with a comparatively small number 1500 volts, so that a single break of from 1¼ to 1½ in. will be sufficient for the contacts when used in conjunction with an auxiliary magnetic blowout circuit.

---

[1] Circuit Breaker Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

With careful attention paid to design of the contacts in order to reduce the air-gap in the blowout magnet to a minimum, a blowout value of the order of 20,000 ampere-turns at 5000 amperes will be sufficient where high-speed interruption is confined to current values of from 3000 amperes upward. For small kilowatt capacity machines, where high-speed action is desired for currents as low as 800 to 1000 amperes, blowout values must be materially increased to assure satisfactory results in operation.

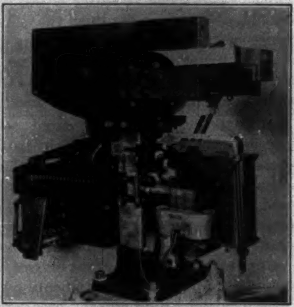

FIG. 1—HIGH-SPEED CIRCUIT BREAKER FOR 1500-VOLT D-C. RAILWAY SERVICE, CIRCUIT RATING, 3000 AMPERES

Blowout values of this order may be expected to remove an arc from the contact surfaces and transfer it to arcing horns during the first one-quarter inch of contact travel, so that all of the mechanical force applied to produce acceleration of the moving contact on opening should be concentrated so far as possible in this first one-quarter inch of travel and no further interest need attach to the speed of contact opening beyond this point except to insure that there is sufficient contact separation at the time the arc is extinguished to prevent reestablishment of the circuit. The problem then becomes one of acceleration rather than of high speed, since the accelerating force, while quite large, is not applied for a sufficiently great length of time to produce relatively high speeds. Fig. 2 shows the speed of contact travel at various points in the opening stroke up to one inch on a high-speed breaker designed for 3000 ampere d-c. service.

From this it will be apparent that for d-c. service, any feature which detracts from the amount of contact opening during the first 0.004 sec. after the breaker is tripped will hinder the limitation of current very materially. For instance, an auxiliary arcing contact with a quarter-inch lead would result in a complete loss of this time and a flexible brush contact involving an eighth-inch follow-up would result in a loss of nearly 70 per cent of it. Consequently, where feasible, a solid butt contact without auxiliary arcing tips becomes very desirable. Such a contact also permits working to a much higher current density, resulting in a very considerable reduction in the mass to be accelerated since there is no flexible laminated copper present to suffer possible deterioration under excess temperatures. Given a design in which the flexibility necessary to secure adequate contact pressure is supplied by a spring, working through leverage if necessary, the solid butt contact becomes entirely feasible for this application.

The resulting design is, then, a solid butt contact which carries main-circuit current, on which the arc is drawn as soon as mechanical separation of the contact surfaces is obtained, and from which the arc is transferred to arcing horns very early in the opening stroke by a powerful blowout magnet. These arcing horns are an integral part of the arc chute and care must be taken in the design to arrange them so as to secure the greatest possible increase in the length of arc in the shortest interval of time. Test data indicate that a d-c. arc becomes unstable at potentials in the order of 30 to 35 volts per in. of length which would require stretching a 1500-volt arc to a length of approximately 45 in. for interruption. The arc chute for a 1500-volt breaker must then be designed to accommodate an arc of this length with sufficient additional capacity to cover such overvoltages as may be encountered on highly inductive circuits without permitting the arc to extend outside of the chute to such an extent as to strike other potential points. Care must be taken also in the design of pole faces to secure a properly graduated blowout field over the arcing area. This field must be intensified at the point of origin of the arc, but must shade off rather rapidly after the length of arc has reached a point corresponding to the limitation of current rise in order that the rate of fall of current may not be too rapid as the interrupting point is approached. Tests with breakers of this type indicate that a very fast falling current may be accompanied by an overvoltage surge of such magnitude as to cause severe potential stresses on the machine. From this point of view, a breaker which interrupts a given circuit in 0.015 sec. may impose materially less stress on the machine than one which gives complete interruption in considerably less time.

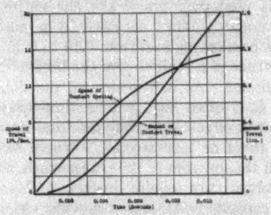

FIG. 2—SPEED OF CONTACT OPENING FOR HIGH-SPEED D-C. CIRCUIT BREAKER. CURRENT CAPACITY, 3000 AMPERES

From time to time, various arrangements of arc splitters have been incorporated in d-c. arc chutes in an attempt to supply a mechanical means of lengthening the arc rapidly. Difficulty has been encountered in the use of such splitters due to their choking the expulsion of gases from the vicinity of the contacts with consequent re-ignition of the circuit across the points of the arc splitters or across the contacts themselves. The tendency in modern breakers is toward the removal of all obstructions in the chute to permit the free action of convection currents following the rise of the arc and thus provide adequate ventilation for removing the gas field from the vicinity of the contacts as the arc extends.

As to mechanical operation of the contacts, the breaker must be capable of high-speed interruption in the event of being closed against a fault in service, which requires that it be trip-free in action. This is best accomplished by a multiple-stage closing stroke through a floating lever. Fig. 6 shows the arrangement of such a mechanism in which the closing power is applied at one end of the floating lever and utilized to seal the holding armature while the contacts remain in the open position. A set of closing springs is also extended by this closing solenoid stroke. Upon de-energizing the solenoid, these closing springs serve the threefold purpose of closing the contacts, extending the opening springs, and retrieving the solenoid core. Thus by utilizing various pin centers in the floating lever as fulcrums at different stages of the movement, the contacts become trip-free at any point in the closing stroke. The excess of power in the closing springs over that of the opening springs provides the flexible means necessary for maintaining adequate contact pressure referred to previously. While tending to maintain the contacts in the closed position, these closing springs in no way hinder the opening movement since the point at which the holding-in power is applied becomes a fulcrum for the opening movement as soon as the holding armature is released.

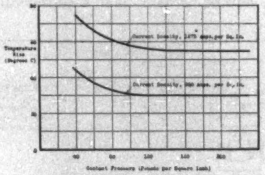

Fig. 3—Relation of Temperature Rise to Contact Pressure for Solid Butt Contacts in Air

Fig. 3 shows the effect of contact pressure on temperature rise with the use of solid butt contacts in air for current densities per square inch of contact surface of the order of magnitude ordinarily used in breakers of this type for railway service. It will be noted that the temperature rise decreases quite rapidly with the increase in pressure through the lower range but the decrease is less marked at pressures of from 80 to 100 lb. and very little improvement is shown beyond this point for pressures up to well over 200 lb. per sq. in. From these curves it will be apparent that the method of securing contact pressure by maintaining a balance between two springs may be relied upon to give adequate pressure, and at the same time provide a considerable range in adjustment of the springs for other purposes. Comparative tests have been made to determine the ability of this type of contact to carry heavy current loads after repeated drawing of arcs from the main contact surfaces. The temperature rise was determined by test for a breaker with new contacts worked at a current density of approximately 1200 amperes per sq. in. of contact surface, and a second test made on the same breaker after it had been used for short circuit test purposes until the contact surfaces showed no indication of their original machining, and without any cleaning of these surfaces. This second test showed approximately 15 per cent less current density for the same temperature rise. The contacts should, then, be designed with sufficient factor of safety to permit an equivalent increase in temperature rise before reaching final temperatures at which deterioration of the contact material may begin.

In view of the rigid requirements as to time for the operation of high-speed breakers in d-c. circuits, the delay involved in releasing a mechanical latch of the conventional type becomes a severe penalty when this device is used. An arrangement which has been found well adapted for retaining the d-c. high-speed breaker in its closed position comprises a stationary holding magnet and an armature linked to the operating levers, so arranged that upon the decay of holding flux, due either to the interruption of holding current or to demagnetization from some other source, the armature will release and permit the contacts to open under the influence of the opening springs. As the armature must be given a high rate of acceleration, its mass will be reduced as much as possible, resulting in its being worked well up toward the knee of the saturation curve.

This being a protective breaker, designed to limit the rise of short circuit current in the shortest possible interval of time after the occurrence of a fault, some form of tripping other than simply the consequence of amperes of overload becomes essential. An overload device is inherently unable to determine whether or not a load is to become a hazard until it has already reached the hazardous point, and this in the case of a short circuit of fast-rising current is far too late to limit that rise satisfactorily. A discriminating device known as an inductive shunt, whose action is based on the rate of rise of current, is best adapted to the requirements. The main power circuit in the vicinity of the holding magnet is divided into two parallel paths, one of which passes through the air-gap of the holding magnet while the second by-passes this magnet. Under conditions of steady load or of slowly-rising load, the by-pass lead carries a relatively large proportion of the current and the air-gap lead a small proportion which, due to the arrangement of potentials, produces a flux in the holding armature opposed to that generated by the holding coil current. So long as steady conditions or slowly-rising conditions obtain, the holding coil predominates and the armature holds the contacts in the closed position. The by-pass lead is, however, so arranged as to be acted upon by a laminated iron circuit which in the event of a rapid rate of rise in current acts to force a comparatively large proportion of the load through the air-gap lead momentarily. This results in a sudden increase in the demagnetizing flux in the holding armature which releases it and allows the contacts to open due to the action of the opening springs.

It will be apparent that with this arrangement, a balance may be secured between the holding coil flux and that generated by the action of the inductive shunt so sensitive as to permit the breaker to open with very slow rates of rise of main circuit current. General operating conditions in d-c. railway service, however, require that the high-speed breaker shall not open on legitimate changes in load such as the acceleration of a train, and some point just above the fastest rate of rise obtainable from train acceleration becomes the lower limit at which this breaker may be allowed to open under changing load conditions. It will be understood that in operating service a fault may occur which due to circuit conditions, generally a matter of distance from the station, gives a rate of rise of short circuit current less than the rise from nearby heavy train acceleration and that the high-speed breaker may not be expected to interrupt such short circuits when the balance between holding and demagnetizing flux is so arranged as to open only on a higher rate of rise. Some other discriminating device must be installed in the circuit for this purpose. It will also be obvious that this degree of sensitivity in the breaker may be dulled further over a wide range until the point is reached where it has become practically an overload breaker with no discriminating characteristics and with very little ability to protect a commutating machine. It should be borne in mind that where this type of breaker is applied for the performance of functions other than opening on rate of rise of current, some degree of discrimination will be sacrificed with a corresponding loss in the protective function for which it was primarily designed.

FIG. 6—DIAGRAMMATIC SKETCH SHOWING MULTI-STAGE CLOSING MECHANISM FOR HIGH-SPEED, TRIP-FREE ACTION

converter substation giving a current rise of the order of thirteen million amperes per second show limitation of short circuit current across the buses to slightly less than 300 per cent of normal load. For machines whose characteristics give a slower rate of rise such as a d-c. generator, the time of limitation and interruption of current will be proportionately longer while still providing adequate protection to the commutating apparatus. Fig. 5 is an oscillographic record of high-speed breaker performance on heavy current at 600 volts.

For alternating-current railway service, the high-speed breaker assumes an entirely different form. The majority of such applications today are main-line electrification projects fed from overhead contact lines at 11,000 volts, 25 cycles, with frequent movements of heavy trains. On such applications the use of high-speed breakers capable of limiting the duration of short-circuit current is of considerable advantage in lessening the shock to the system, in reducing the damage to contact lines, and in minimizing the possibility of synchronous machines falling out of step. Furthermore, the use of high-speed breakers facilitates the coordination of propulsion and communication circuits when they are involved in an inductive exposure. As this propulsion service is almost entirely confined to a frequency of 25 cycles, one-cycle operation allows 0.04 sec. for the detection and interruption of a short circuit. The high-speed circuit breaker shown in Fig. 7 has been developed to meet the requirements of such applications. Essentially a single-pole oil circuit breaker of the conventional gravity break type, it differs from the normal-speed oil breaker in that it carries: a high-speed shunt-tripping device; provision for a high acceleration of the moving contact; an auxiliary magnetic blowout circuit for lengthening the arc rapidly; it is actuated by a specially-designed high-speed relay. Unlike the d-c. high-speed breaker, it carries no discriminating features in itself but is actuated solely by the high-speed relay in which are incorporated all the characteristics necessary for such selectivity in tripping as may be desirable for any given application. The breaker carries a voltage rating of 15 kv., although all electrical clearances outside the interrupting chamber are adequate for 37-kv. service. It is designed for steady current loads of 1500 amperes at 25 cycles, and has an interrupting capacity of 50,000 amperes at 12 kv.

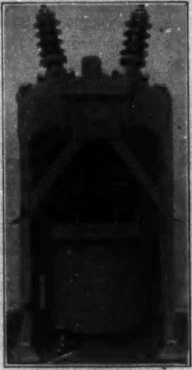

Fig. 7—Front View of High-Speed Circuit Breaker for A-c. Railway Service, Rating 15 Kv., 1500 Amperes, 25 Cycles

From the design point of view, this breaker presents a problem somewhat different from that involved in the d-c. high-speed breaker. The holding magnet raises problems due to directional characteristics when applied to a-c. circuits that require considerable in the way of added complications to overcome. Furthermore, this form of tripping does not carry inherently the degree of selectivity desirable for the majority of a-c. railway applications and some additional relaying becomes advisable when it is used. Consequently, a quick-acting mechanical latch released by a high-speed trip magnet, which in turn is actuated by a high speed selective relay external to the breaker, becomes not only feasible but desirable from the point of view of close accurate settings for selective tripping.

For like reasons the contacts in this breaker may be designed differently from those of the d-c. high-speed breaker. To perform the function for which it was developed, the breaker is placed in the contact line feeder circuits where the current loads are relatively light as compared with the heavy machine loads of d-c. railway circuits. The flexible brush form of contact may be used here without imposing great burdens in the form of mass, to be accelerated at high speed, provided the brush is used as the stationary element of the contacts. By a liberal design of this stationary element, the moving element may be worked at a comparatively high current density, depending on the stationary copper to conduct heat away, and the mass to be accelerated thus reduced to proportions that may be handled with reasonable facility.

The breaker must be trip-free in order to interrupt the circuit at high speed in the event of being closed against a fault. In the conventional form of oil circuit breaker the trip-free point is normally placed at the closing mechanism in order to combine the closing and tripping features in a single unit and to insure simultaneous action in all phases of a multiple-pole breaker. In this country at the present time, a-c. railway applications are, however, practically all on a single-phase basis so that a single-pole breaker meets all requirements. The trip-free point may then be placed as close to the moving contact element as mechanical and electrical requirements will permit, provided the tripping mechanism is placed at this point also. The point best suited to all these conditions will be found at the upper end of the contact lift rod, requiring only the contact, its lift rod, and one lever to be accelerated on opening. The accelerating force may be supplied by a helical spring concentric with the lift rod.

Fig. 8 shows in graphic form the accelerating force in pounds for each pound of mass accelerated necessary to produce various speeds at the end of the first one-quarter inch of contact travel in oil. It may be noted that approximately one-third of the mass of the spring itself must be included as mass to be accelerated when designing these springs. As in the case of the d-c. breaker, this is a problem of high acceleration rather than high speed of travel since interest in the speed of opening is confined largely to the first one-quarter inch of travel, that is, the amount of travel necessary to part the contacts and produce an arc. Through the action of the blowout magnet, this arc will be transferred to arcing horns and lengthen rapidly independent of the speed of contact travel. Of course, one terminal of each arc must be maintained on the moving contact, but tests have demonstrated that with the moving contact shaped to provide a horn, the arc terminal will travel on this horn ahead of the contact under the action of a blowout field.

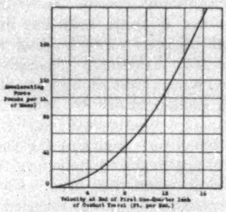

FIG. 8—RELATION OF ACCELERATING FORCE TO CONTACT VELOCITY. (IN OIL)

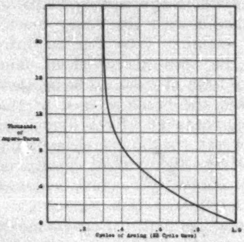

FIG. 9—VARIATION IN DURATION OF ARCING WITH HIGH-SPEED A-C. CIRCUIT BREAKER FOR VARYING VALUES OF MAGNETIC BLOWOUT FIELD

Fig. 9 shows the effect of a blowout field on the duration of arcing in a high-speed oil circuit breaker. The effect is quite marked for the lower values of field strength but the curve finally becomes asymptotic as the field is increased in strength and a point is eventually reached at which no further reduction is obtained in the period of arcing by increasing the excitation of the blowout magnet. This point, however, is well within a half-cycle of arcing on a 25-cycle wave and meets the requirements of present-day a-c. railway service.

The design of the blowout magnet will vary somewhat depending on the service in which the breaker may be applied. Where only low values of short-circuit current are to form a large proportion of the interrupting duty, a full iron return circuit may be used to work well below the saturation point. If heavy short circuits are anticipated, better results will be obtained with a magnet having a small section of return circuit designed to saturate at six to eight thousand amperes and forcing an air return path for the high current values. This is in order to eliminate the possibility of lengthening the arc unduly fast for very high current values having a heavy blowout force inherent in themselves. Care must also be taken in the design of this magnet from the point of view of temperature rise, bearing in mind that it must be excited by a series a-c. coil, and adequate means provided for radiation of heat. In this connection it may be noted that this application in railway service imposes a duty on trolley feeder breakers somewhat more severe than the standard N. E. M. A. duty cycle in that they may be called upon to perform more than the stipulated two OCO operations at full rated current, or a proportionately greater number at lesser current values, before an opportunity is afforded of renewing the oil. Provision should then be made in the design for a substantially larger amount of oil in the interrupting chamber than is required for conventional breakers of the same interrupting rating, and this increased body of oil will be of material benefit in taking care of heat radiation.

The design of mechanical latch for retaining the contacts in the closed position must receive careful attention in order to insure that the time of unlatching is reduced to a minimum. The conventional form of circuit breaker latch with right-angled holding face involves inherent time delay in that the holding face must be moved well over the center of the roller before opening motion can start. With the heavy accelerating spring used, this form may also result in heavier latch loads than are desirable for high-speed tripping.

Fig. 10 shows the details of a high-speed latch mounted in a common frame with the tripping magnet, forming an integral unit. The roller element of this latch is mounted on a floating lever linked to the contact lift rod and accelerated with it on opening. The primary latch presents an inclined surface to this roller in such manner as to give an angle of thrust well inclined toward the open position so that the movement of the floating lever and roller in opening starts simultaneously with the movement of the latch in releasing. This primary latch is maintained in the closed position by a secondary latch requiring only about one-eighth of an inch movement to release. In operation, the tripping magnet raises the secondary latch, allowing the primary latch to release under the impulse of its own latch load and at the same time permitting the floating lever and contact to start toward the open position. The floating lever is retrieved to the latched position with the contacts open and revolved about the latch roller as a fulcrum to the closed contact position by the closing mechanism. An over-center toggle in the operating linkage maintains the breaker in the closed position until it is again tripped. Thus, by utilizing different centers in the floating lever as a fulcrum at different stages of the movement, trip-free action is obtained at any point in the closing stroke.

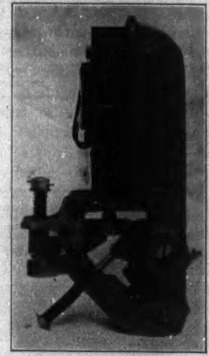

Fig. 10—Shunt Tripping Magnet and Latch for High-Speed A-c. Circuit Breaker

A d-c. shunt tripping magnet designed for use with the high-speed oil breaker is shown in Fig. 10. This magnet while necessarily enclosed within the breaker chamber, should be so located as to be freely accessible upon the removal of a cover in the main breaker casting. Fig. 7 shows a view of the breaker with the cover removed, exposing the magnet. This magnet is of the conventional laminated form, rather liberal in design so far as the magnet itself is concerned, but with the mass of the armature reduced to a minimum since it must be picked up very quickly. With the design of latch used here, the air-gap may be reduced to about five-sixteenths of an inch with a working travel of from one-eighth to three-sixteenths. To obtain the most suitable magnet, a low resistance coil will be necessary but external resistance may be used in the circuit where it is desired to maintain tripping current within the limits of battery supply for simultaneous tripping of a number of breakers.

Fig. 11 shows a view of the mechanism housing of a high-speed a-c. breaker with the covers removed. A closing solenoid, designed for 125-volt d-c. control, is mounted as an integral part of the breaker unit together with the necessary control panel, rotary type auxiliary switches, and a heater unit to prevent condensation inside of the housing under certain atmospheric conditions. As in the case of the d-c. high-speed breaker, such auxiliary switches as operate in unison with the main breaker contacts are moved to one position by a linkage operated by the closing of those contacts but on the opening of the breaker contacts, are retrieved to the opposite position by a spring. This is to reduce the load on the main accelerating spring when opening as well as to relieve the switches of the mechanical stresses incident to high-speed operation.

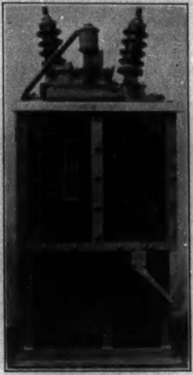

Fig. 11—Rear View of High-Speed Circuit Breaker for A-c. Railway Service Showing Control Mechanism

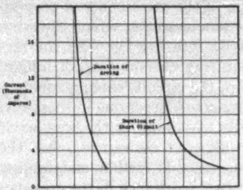

Fig. 12—Time Characteristics of High-Speed A-c. Circuit Breaker on Short-Circuit Test.
Including Time of Relay and Shunt Trip

Fig. 12 shows the time characteristics of a high-speed a-c. circuit breaker on short-circuit test, including the operating time of the high-speed relay and shunt trip. This breaker is designed to interrupt short-circuit currents of from 2000 amperes upward in 0.04 sec. (one cycle on a 25-cycle wave) after the occurrence of a fault. For current values of from 15,000 amperes upward, the breaker operates rather consistently in one-half cycle when the short circuit originates at or shortly after the zero point of the wave. In the event of the fault occurring relatively late in any given half-cycle, it will often persist through the next half-cycle before interruption. For current values of less than 2000 amperes, the time of interruption will still be of the order of one cycle but due to the inherently low blowout values involved as well as the necessity of varied relay settings to secure selectivity, the short circuit may persist for an additional half-cycle. Tests made at current values of from 10,000 to 15,000 amperes over a voltage range of from 1500 to 12,000 volts show no appreciable difference in the duration of arcing, indicating that within the range of service voltage in present-day railway applications, the time of circuit interruption for a breaker of this type is independent of initial circuit voltage. Fig. 13 is an oscillographic record of performance on short-circuit test at 11,000 volts.

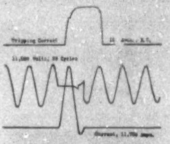

Fig. 13—Oscillogram Showing Performance of High-Speed A-c. Circuit Breaker on OCO Duty Cycle

A word as to the problems confronting the design engineer in attempting to apply high-speed breaker operation of this type to higher a-c. voltage service or to multiple-phase circuits. It has been pointed out in this paper that an auxiliary blowout field is essential to high speed interruption at the lower current values. Obviously, to be efficient the blowout field must be so distributed as to supply not only an intense field at the point of origin of the arc but also a properly graduated field over the whole area in which the arc may exist at any stage of its interruption. As the service voltage increases, requiring the drawing of longer and longer arcs to rupture the circuit, these magnets must control ever increasing areas, becoming in themselves more and more unwieldy to support in the breaker chamber with adequate insulation clearances. As the magnetic structure thus extends farther and farther downward into the clear break distance in the open position of the contacts in the effort to control the arcing area, the travel of the contacts must be increased by a safe amount to secure the necessary break distance for preventing reestablishment, thus increasing the over-all height of the breaker structure and, incidentally, its cost. As we approach the point in service voltage at which static shielding becomes necessary, these problems become so serious as to suggest seeking some method of securing the desired circuit conditions other than by the use of high-speed breakers.

As to application in multiple-phase circuits, it is obviously unsafe to permit the contacts of any single pole of a multiple-pole breaker to be operated independently of the other poles. This means that the tripping point must be so located as to control all of the linkage inside of all pole units as well as such linkage outside of these units as may be necessary to operate the several poles from a central point. This involves at once an increase of many times the mass to be accelerated at high speed and calls for a class of mechanical design not hitherto used to any extent in switching apparatus. At the best, there must be a very material increase in the power of accelerating springs used, and this power must again be reflected in increased closing loads creating an additional problem not only of design but of application as well.

In general the conclusion may be drawn that from the design point of view, adequate high-speed circuit breakers can be supplied to meet the present-day requirements for machine protection in d-c. railway circuits as well as such requirements as may be foreseen for some time to come. Also, adequate high-speed circuit breakers can be supplied to meet the requirements for protection for 25-cycle, single-phase, railway electrification work up to 12,000 volts. High-speed a-c. breakers for the next one or two steps above this in operating voltage for single-phase railway service seem within easy reach although not developed at the present time due to an absence of demand for breakers at these voltages. A-c. breakers of this type for high-tension circuits, or for multiple-phase circuits at any voltage are not at the present time available, and seem to present problems requiring a substantial amount of development work before they may become available.

# Operating Experience with High-Speed Oil Circuit Breakers

BY B. F. BARDO[1]
Non-member

***Synopsis.**—This paper outlines the experience of the New York, New Haven and Hartford Railroad with three high-speed oil circuit breakers which were installed in 1925 to serve an electrified branch line carrying freight and passenger traffic, both local and through.*

*Satisfactory operation of paralleling commercial communication circuits, as well as of its own, presented an immediate problem, which after study outlined in the paper, finally yielded, and the answer, in part, was high-speed circuit breakers. The electrical and mechanical characteristics of these are set forth in detail and illustrated.*

*A number of tests of the circuit breakers and communication circuits made by short-circuiting the 11,000-volt lines on the branch showed currents up to 3000 amperes, and openings in from one-half to one and one-half cycles, with satisfactory operation of commercial and railroad communication plant.*

*A detailed record of the service operations of the circuit breakers along with a statement of failures is given. It is proper to say that the latter were more numerous in the early days of their use than they have been in recent months, and that a number of the faults are chargeable to the railroad's urgent need for the equipment, thereby considerably limiting the development and testing time desired by the manufacturer.*

*While it was not discussed in detail in the paper it goes without saying that in the design and installation of the circuit breakers safety was a paramount consideration. The illustrations will provide an index of this in the general arrangement of equipment, and also in the screen placed horizontally around the structure at the floor level to prevent curious small boys from climbing in to investigate.*

### CHARACTER OF SERVICE AND ELECTRIFICATION

BEFORE discussing in detail the New Haven Railroad's experience with high-speed oil circuit breakers, it will be of interest to review briefly the reasons for their installation.

In the latter part of 1924, decision was made to electrify the Danbury Branch, comprising 23.82 mi. of main, along with 5.1 mi. of passing or side track between South Norwalk, Conn., in the New Haven's electric zone, and Danbury, Conn. The service at that time consisted of an average of six passenger trains, two through freight trains, one milk train, and one local freight train per day in each direction. The system of electrification was to be essentially the same as that in use on the main line, between New York and New Haven, Conn., namely, 11,000 volts, single-phase, 25 cycles, using an overhead contact wire and track rail return. A schematic diagram of the distribution system, as finally adopted, is shown in Fig. 1.

### COMMUNICATION FACILITIES

On the branch to be electrified the New Haven had open wire communication circuits used by the Western Union Telegraph Company and itself respectively. Furthermore, on private property immediately adjoining and paralleling the company's right-of-way for nearly half of the distance and on public highway for the balance of the distance was a commercial open wire telephone line, this being more or less spread out in the various towns along the way. Therefore, an immediately important problem was to decide how best to provide for satisfactory operation of paralleling commercial and its own communication circuits, and at the same time not make the electrification itself too involved, from an operating standpoint, or too expensive from a maintenance standpoint.

### STUDIES MADE

Various schemes were studied involving the use of reactors in the trolley and feeder circuits at South Norwalk (see Fig. 1), along with booster transformers, balancing transformers, and supplementary return circuit, independent of the running rails, the induced voltages and other effects in each case being based upon the average duration of short circuit as determined by oil circuit breakers standard elsewhere in the electrified zone. The results of these studies indicated that the electrification and the communication circuits could be so designed that they would operate satisfactorily, using existing standard circuit breakers to interrupt short circuits, but this involved the installation of a number of series booster transformers, which were not desirable from railroad operating point of view.

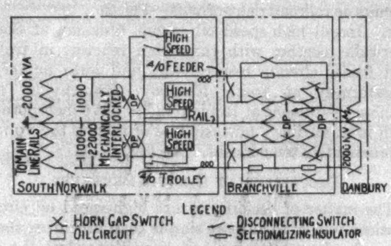

FIG. 1—NEW YORK, NEW HAVEN & HARTFORD RAILROAD COMPANY, DANBURY BRANCH

Schematic diagram of electric power distribution

At this point the installation of high-speed oil circuit breakers at South Norwalk was proposed, with the understanding that while they would not decrease the magnitude of the voltage induced in the communication circuits, yet by virtue of their quick operation, they would materially reduce interference in both railroad and commercial communication circuits. It was decided that circuit breakers of this kind would be more desirable than booster transformers, and therefore the following program, satisfactory to all interests, was adopted:

---

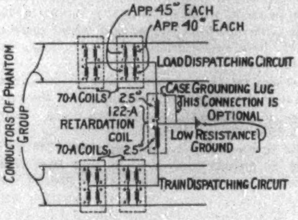

Fig. 2—Danbury Branch—Communication Circuit Drainage

a. Place paralleling commercial communication circuits in cable on the public highway.

b. Install adequate drainage on communication circuits on railroad right-of-way—Fig. 2.

c. Install high-speed oil circuit breakers at South Norwalk together with three-ohm reactor, in trolley and feeder circuits respectively, and auto balancing transformers at South Norwalk, Branchville, and Danbury,—the one at Branchville to have incorporated with it an auxiliary unit capable of raising the voltage approximately ten per cent. See Fig. 1.

## Description of Circuit Breakers

The matter of deciding to use high-speed oil circuit breakers proved to be more simple than procuring them. Some development work had been done, but the circuit breaker was not then in commercial production, and considerable pressure was required to convince the manufacturer that three should be built. This, however, was finally arranged, and they were built early in 1925.

Each of these carries a normal rating of 800 amperes at 16,500 volts, 25 cycles. The maximum interrupting capacity approximates 35,000 amperes. Direct current is used for control normally at 250, but with a standby supply at 500 volts. The tripping operation is started by solenoids, of which there are two, connected in parallel on the lower, and in series on the higher voltage. The actual tripping work is done by spiral springs, these being compressed during the closing operation by a 110-volt, 25-cycle, single-phase motor operating through a train of gears. The circuit-breaking mechanism is in the shape of an inverted letter "T," with a blowout coil, in series with the circuit to be broken, on each stationary contact. The entire assembly is immersed in insulating oil, and enclosed in a substantial sheet steel cylindrical tank, suitably vented. Two condenser type bushings, each terminating in a removable stationary contact within the tank carry the current, and the whole is supported by four angle steel legs to which are bolted cast iron feet. There is an individual current transformer of the outdoor type for each circuit breaker, which is directly connected to an overload coil, also for each circuit breaker. Irrespective of the location of the short circuit, whether on trolley or feeder, it is desirable to open both trolley and feeder circuit breaker, and this is accomplished by auxiliary contacts on each overload relay so connected that when one circuit breaker opens the other will immediately follow, thus clearing the line.

## Installation

Three circuit breakers were installed on a steel platform 27 ft. by 10 ft., with reinforced concrete house directly underneath, and change-over horn-gap switches directly overhead. Reference to Fig. 1 will show that any of the three circuit breakers may be used in any combination, two at a time. Fig. 3 shows an elevation of circuit breakers as installed, and Fig. 4 of the entire substation of which they are a part.

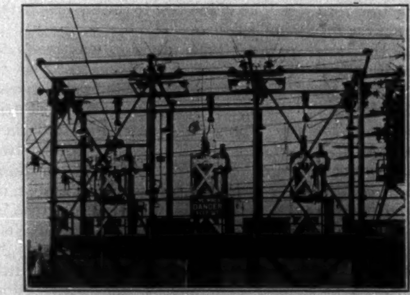

Fig. 3—High-Speed Circuit Breakers, South Norwalk

## Communication Line Protection

The method of applying drainage to communication circuits is as follows: The physical circuits are drained by two No. 70-A repeating coils so connected that both primary and secondary windings are in multiple. The midpoints of these windings are then connected to ground through one winding of a No. 122A coil, which acts also as a drain on the phantom circuit. A combination such as this was installed at each end of the branch and at six intermediate points approximately uniformly spaced from each other.

## TESTS

In the early part of October 1925 a series of tests was made jointly by the American Telephone and Telegraph Company and the New Haven to determine the extent to which the high-speed circuit breakers, as well as the communication line drainage, etc., contributed to satisfactory operation. Oscillograph records of these tests were made, three of which are reproduced here. They are:

FIG. 4—SUBSTATION AT SOUTH NORWALK

Fig. 5—A short circuit at Danbury, 23.8 mi. from the oscillograph, the latter being at point of supply, South Norwalk. The circuit was opened in one cycle (1/25 sec.) and the current reached a maximum of 1000 amperes.

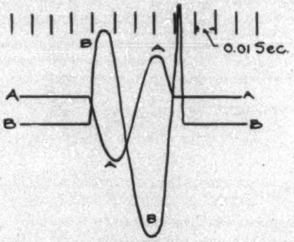

FIG. 5—SHORT CIRCUIT AT DANBURY—23.8 MI.

A. Trolley current—maximum 1000 amperes
B. Volts across drainage at South Norwalk—maximum 48.7 amperes

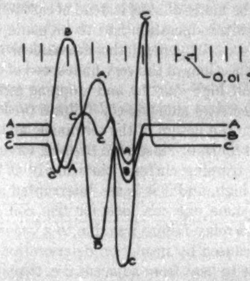
Fig. 6—A short circuit at Wilton, 7.4 mi. from South Norwalk, showing an opening in one and one-half cycles at a maximum 540 amperes.

Fig. 7—A short circuit at South Norwalk, one-half mile from the oscillograph, showing the circuit open in one-half cycle, the maximum current being 3030 amperes.

## CIRCUIT BREAKER OPERATION

Considering the three circuit breakers as a group, it may be noted that since being put in service in July 1925 the operation has been as follows:

| | |
|---|---|
| Total number of operations on grounds | 717 |
| Ave. number of operations on grounds per circuit breaker | 239 |
| Total number of other operations to 1-1-28 | 750 |
| Ave. number of other operations per circuit breaker | 250 |



Note - Behavior of B & C probably transient effect of Trolley & Feeder Circuit Breaker Openings

FIG. 6—SHORT CIRCUIT AT WILTON—7.4 MI.

A. Feeder current—maximum 560 amperes
B. Track current—maximum 685 amperes
C. Induced voltage—maximum 1420 amperes

The circuit breakers have not operated faultlessly and therefore the third, or so-called spare circuit breaker, has been of real use, but this was to be expected. There has been on the circuit breakers as a group, since their installation, a total of 25 operating failures distributed as follows:

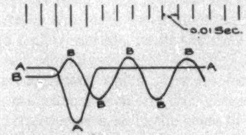


FIG. 7—SHORT CIRCUIT AT NORWALK—0.5 MI.

A. Trolley current—maximum 3030 amperes
B. Induced voltage, S. N. E. Tel. Co.—maximum 180 amperes.

| | |
|---|---|
| Trip coils | 5 |
| Mechanical parts | 5 |
| Closing motor | 2 |
| Overload relay | 1 |
| Indicating switch | 2 |
| High-tension terminal | 1 |
| Unknown | 9 |
| Total | 25 |

Of the above failures those due to mechanical causes have been most difficult to find. Adjustment in length of operating rod had to take into consideration proper sequence of events as between main and auxiliary contacts, along with irregularities on the main contacts due to arcing. If this operating rod length was not correct within fairly close limits the circuit breaker would not close and latch, although it would open satisfactorily. The forged steel spiral-spring ends in the opening mechanism received severe punishment and had to be made heavier. Likewise the foot castings on the legs had to be made of steel instead of cast iron, and the indicating switch operation had to be made somewhat more positive. In general the mechanical difficulties have been reflections of the very high speed of operation, with resultant high starting and stopping stresses.

On the electrical side trip coil failures predominated, due partly to the design of the terminals, and partly to the fact that for some reason the tripping circuit did not open. The tripping current, particularly at 250 volts, is relatively high, and if it is not interrupted as soon as its work is done one can look for trip coil difficulty. The overload relay failure was due to a ground on one of its leads caused by insulation deterioration which in turn was due to heat from adjacent d-c. tripping circuit arc. Barriers have eliminated the possibility of further difficulties due to this source. The motor failures were such as are sometimes found in motors of this nature and involved adjustment of short-circuiting device and cleaning of commutator.

In general, the statement is justified that most of the faults uncovered by our operation would not have appeared if the manufacturer had been given more time to develop the design and test it completely before installation.

### OPERATION OF COMMUNICATION CIRCUITS

It may be of interest to note that the program outlined in paragraph three, parts a, b, and c, has resulted in satisfactory operation to commercial as well as railroad communication circuits.

### ACKNOWLEDGMENT

The writer desires to acknowledge kind assistance of Messrs. H. A. Shepard, general superintendent of electric transmission and communication department, S. Withington, electrical engineer, as well as his assistant, H. Brown, and A. R. Belmont, communication engineer.

## Discussion

For discussion of this paper see page 1311.

# Arrangements of Feeders and Equipment for Electrified Railways

BY R. B. MORTON[1]

Fellow, A. I. E. E.

***Synopsis.**—This paper outlines the general requirements governing arrangements of distribution system and substation equipment for electrified railways. By way of illustration it presents a general description of the conversion and distribution facilities as recently installed in the electrification of the New York Connecting-Long Island Railroad to Bay Ridge, and in the electrification, now nearing completion, of the Philadelphia-Wilmington and West Chester lines of the Pennsylvania Railroad.*

---

## INTRODUCTION

SUBSTATION equipment necessarily includes conversion apparatus required to translate the power received over transmission lines into suitable form for delivery to the contact system. Such apparatus is usually provided in units so proportioned as to load capacity that the outage of any one unit will not place limitations to the movement of traffic.

Switching equipment must be provided which, in the event of short circuits, will quickly and automatically interrupt the supply of power, and so confine the effect of such interruption as to cause the least practicable disturbance to movement of traffic. Although in practise it is necessary to include switching apparatus of more or less complexity, the ideal switching equipment would be none at all. It is obviously desirable to keep the switching equipment as simple as the nature of traffic requirements will permit.

The several examples of railway electrification, to which reference is made in this paper, are of a type utilizing the single-phase a-c. system of traction, but some of the features of switching arrangements herein described may also be applied in a d-c. system. Essentially in a d-c. system of traction there must be interposed between the step-down transformers and the trolley bus, suitable rectifying apparatus, such as mercury vapor rectifiers, motor-generators, or rotary converters.

There may be said to be at least four rather distinct methods of arranging the switching equipment in substations, namely:

1. An arrangement which provides for switching, under load, the transmission circuits, high and low sides of transformers and trolley feeders, as in the case of the original Paoli-Chestnut Hill electrification of the Pennsylvania Railroad (Fig. 1).

Virginian Railway Electrification

2. An arrangement which provides for switching on the high tension side only for controlling both transmission and trolley circuits, as in the case of the Virginian Railway (Fig. 2).

3. An arrangement which provides for switching, under load, the transmission and trolley feeder circuits, but not the transformers, as in the cases of the original electrification of the Elkhorn Grade on the Norfolk & Western Railway (Fig. 3) and the New York Connecting-Long Island Railroads (Fig. 5).

4. An arrangement which provides for switching under load, on the low tension side only, for controlling both high-tension and low-tension circuits, the transformers being switched and regarded as a part of the transmission system, as in the case of the recent Pennsylvania Railroad Suburban and Through Electrification (Fig. 7).

In the selection of a scheme of distribution for a rail-

way electrification, the principal governing factors, not necessarily in the order of their importance, may be listed as follows: source of power; type of system used on any existing electrification to which the new electrification may be joined; maximum concentration of power required for movement of traffic; distances involved, and probabilities of future extension; number of tracks; alinement of railroad and topography of route; property available for substation sites; locations of continuously attended points for control; and relative importance of insurance against traffic delays.

FIG. 3—SCHEMATIC DIAGRAM—MAYBEURY SUBSTATION

Norfolk & Western Railway—Elkhorn Grade Electrification

An example of simplified substation switching equipment will be noted in the electrification of the Virginian Railway. This system has been described in detail in a paper[2] recently presented before the American Society of Civil Engineers. In a typical substation serving the single track portion of this railroad there are provided three oil circuit breakers. Two of these are high-tension breakers, interposed between the transmission lines and the step-down transformers, while the third is a low-tension breaker, serving to equalize the load on the transformer secondaries, or, in the event of one of the transformers or one of the transmission lines being out of service, serving to feed both trolley sections from one transformer. Fig. 2 shows in diagram the arrangement of power connections.

The balancing wire system of distribution for the Virginian Railway electrification was adopted mainly for the following reasons:

With main substations spaced on an average about 20 mi. apart, it was possible, because of the circuitous alinement of the railway, to shorten materially the over-all length of the transmission line. The saving in cost resulting from this factor, combined with the savings due to simplified switching arrangements in substations, partly offset the higher cost of transformers and the cost of the 24-kv. balancing wire. The advantage of a system which materially reduces the effect of inductive disturbances on paralleling communication wires was therefore secured, but, however, at some expense.

In a railway electrification comprising two or more main running tracks, the contact system is usually sectionalized in such a manner that a power outage on one track will not interfere with traffic movements on the remaining tracks. This necessitates a trolley circuit breaker for each trolley section.

The electrification of the New York Connecting Railroad–Long Island Railroad to Bay Ridge, completed and placed in operation during the summer of 1927, may be taken as illustrative in the arrangement of its feeders and substation equipment. A general description of these features may be of interest.

### NEW YORK CONNECTING RAILROAD–LONG ISLAND RAILROAD TO BAY RIDGE

This electrification covers a route 20 mi. in length, extending from a freight terminal yard at Bay Ridge, Brooklyn, to a point of connection with the Harlem River Division of the New York, New Haven & Hartford Railroad at Port Morris, Borough of the Bronx (Fig. 4).

Freight traffic only is handled, with the exception of a few passenger trains daily over the Hell Gate Bridge route, which service was inaugurated in 1917. Freight movements consist of through freight trains operated by the New Haven Railroad between Bay Ridge and Port Morris, way freight and through freights operated by the Long Island Railroad between Bay Ridge and Fresh Pond Junction, and yard switching at Bay Ridge and New Lots.

FIG. 4—MAP OF ELECTRIFIED SYSTEM

New York Connecting Railroad—Long Island Railroad—Bay Ridge Improvement

*Power Supply.* The system of electrification is fundamentally an extension of the New Haven electrification, with 11,000-volt trolleys and 11,000-volt feeders of opposite polarity, forming a 22,000-volt, three-wire system. At present, power for operation is received from the New Haven system, which in turn is supplied principally from its own generating station at Cos Cob, approximately 42 mi. from Bay Ridge, and also in part from purchased power delivered to the New Haven at West Farms, Devon, and New Haven.

---

[2] New York, February 1, 1928, by Mr. George Gibbs.

A variable-ratio frequency changer of 5000 kw. continuous rating at 70 per cent power factor has been provided at East New York, in an addition to one of the substations of the Long Island Railroad. This machine is capable of furnishing the single-phase railway system an emergency supply of power from the 11,000-volt, three-phase, 25 cycle bus, converting the same to power at 11,000 volts, single-phase, 25 cycles, and is also capable of acting as a flexible tie between the two power systems with ability to transfer a desired amount of power in either direction, independently of frequency variations up to a total spread of 6 per cent, equivalent to 1½ cycles. This set is also operated during peak load periods as a synchronous condenser for power-factor correction on the single-phase railway system, for the purpose of improving trolley voltage. When so operated, with the three-phase end of the set electrically disconnected, an automatic voltage regulator so controls excitation as to maintain practically uniform voltage up to a point where the single-phase machine is carrying full rated load of 7000 kv-a. If the system conditions require a loading in excess of 7000 kv-a. to maintain normal voltage, the excitation is so controlled as to automatically droop the voltage, keeping the stator current at an average value corresponding to full load in amperes.

*Substations.* A total of six auto-transformer stations have been provided, separated by an average interval of 3.8 mi. The locations of these substations, number and size of transformers, and number of trolley and feeder circuit breakers in each are as follows:

| Location | Auto-transformers | Trolley breakers | Feeder breakers |
|---|---|---|---|
| Bungay Street | 1—3000 kv-a. | 5 | 6 |
| Bowery Bay | 1—3000 kv-a. | 9 | 6 |
| Fresh Pond | 1—3000 kv-a. | 9 | 6 |
| New Lots ("NO") | 1—3000 kv-a. | 9 | 6 |
| Manhattan Beach Jct. | 1—3000 kv-a. | 7 | 8 |
| Fourth Ave., Bay Ridge | 2—3000 kv-a. | 6 | 4 |

The transformers are of the outdoor type, self-cooling, and have a turn ratio of 22,000:11,000 volts. The rating as an auto-transformer corresponds to a coil rating of 1500 kv-a. for each half of its winding. The transformers are capable of carrying 150 per cent of rated load for one hour, following continuous rated load, and this followed by 300 per cent of rated load for five minutes.

The transformers are connected to trolley and feeder buses through two-pole, 22,000-volt motor operated horn-gap switches, capable of safely rupturing transformer exciting current.

A schematic diagram of one of the substations, indicating the arrangement of connections of trolleys and feeders is shown in Fig. 5. It will be noted that at this substation, two of the four feeders are tapped and the other two are looped. At the next adjacent substations the order is reversed.

Trolley and feeder oil circuit breakers are of compact design, similar to breakers which are used on the New Haven system. They have a current rupturing capacity of about 3000 amperes at 11,000 volts. Short-circuit currents for trolley or feeder short-circuits adjacent to a substation may reach maximum values considerably in excess of this value. In order to avoid imposing on the circuit breakers of the Bay Ridge system, or on the similar breakers of the New Haven system, a current rupturing duty beyond the interrupting capacity of those breakers, an arrangement of oil circuit breakers is provided on the New Haven system at its Cos Cob power plant and at each other point where purchased power is received, whereby a flow of current of the magnitude of a short circuit causes resistances to be momentarily cut into the trolley and feeder circuits at such supply points. This reduces the flow of short-circuit current to a nominal value. The Bay Ridge breakers have been given a predetermined time delay of one second following the occurrence of a short-circuit, before the tripping circuit is completed, which insures that these breakers shall be required to rupture but a comparatively small current. After slightly more than one second, the several resistances are automatically cut-out and normal voltage is restored to the system.

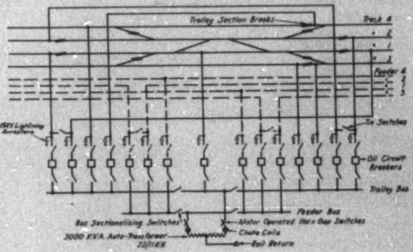

Fig. 5—Schematic Diagram—"NO" Substation

New York Connecting Railroad—Long Island Railroad—Bay Ridge Improvement

All auto-transformer substations are unattended. The circuit breakers and motor operated horn-gap switches in each substation are controlled from a panel mounted in a signal interlocking tower nearest to that station. In the case of Bowery Bay substation it was necessary to utilize a system of supervisory control from Bungay Street tower, a distance of three and a half miles.

*Distribution System.* The feeder side of the three-wire distribution system comprises four 4/0 copper conductors extending the entire length of the line, as far as Bay Ridge substation. These feeders are carried on pin type insulators of 45,000 volts service rating. Between Fresh Pond and East New York is a four-arch tunnel, 3500 ft. long, in the outside walls of which are banks of cable ducts. Through these ducts four paper insulated, lead sheathed cables of 350,000 cm. are used.

The trolley system for all main running tracks comprises a 4/0 bronze contact wire, 65 per cent conductivity, reinforced by a 4/0 copper auxiliary, supported by a 19-strand messenger ⅝ in. diameter, of high strength bronze. In yard construction the copper auxiliary is omitted.

*Track Return.* All rail joints on main tracks are single bonded with a No. 1 bond, gas welded to the head of the rail. In yard tracks one rail only is bonded. Cross bonds are installed at intervals along the main line to cross-connect the mid-points of impedance bonds.

The three-wire system of distribution was selected for the New York Connecting Railroad–Long Island Railroad, Bay Ridge line, mainly for the reason that this electrification is fundamentally an extension of the existing electrification of the New York, New Haven & Hartford Railroad. The distances from the sources of power are considerable, but are within the range of economical transmission for the voltage employed. Circuit breakers of relatively low current rupturing capacity are used because they are adequate for the conditions of power supply and because they afford a considerable saving in first cost as compared with breakers of larger current rupturing capacity.

## PHILADELPHIA SUBURBAN ELECTRIFICATION OF THE PENNSYLVANIA RAILROAD

The electrification of Maryland Division, main line, from Philadelphia to Wilmington, Del., a distance of about 27 mi., and of the Wawa Branch to West Chester, a distance of about 26 mi., is now nearing completion (Fig. 6). Approximately 105 mi. of electrified track are involved in the main line work, and approximately 50 mi. in the Branch.

Substations have initially been equipped for supplying power for the operation of multiple unit trains only, but the Wilmington line has been designed to later form a part of through electrification between New York and Washington, with locomotive operation of main line freight and passenger services.

*Power Supply.* Power for the electrification is supplied by the Philadelphia Electric Company at 13,200 volts, 25 cycles, single-phase, delivered on the bus bars of the Railroad Company's step-up station at Lamokin Street, Chester. Three self-cooled single-phase transformers of 15,000-kv-a. continuous rating are provided for stepping up this power to a transmission potential of 132,000 volts. This transmission potential was selected by reason of the large amounts of power which will be required for the ultimate through electrification, and the considerable distances to be covered.

Initially two transmission circuits of 4/0 copper are provided, which are supported on the catenary structures. Ultimately it is planned that the number of transmission circuits along the main line may be increased to four.

*Substations.* A total of nine substations are provided in which the power is stepped down to a trolley potential of about 11,000 volts. The locations of these stations, number and size of step-down transformers and the number of trolley circuit breakers in each are as follows:

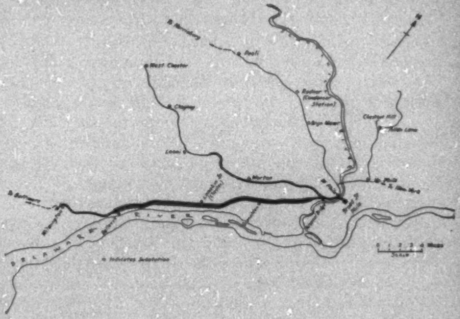

FIG. 6—MAP OF PHILADELPHIA SUBURBAN ELECTRIFICATION, PENNSYLVANIA RAILROAD

| Location | Transformers | Trolley breakers |
|---|---|---|
| Wilmington | 2—4500 kv-a. | 4 |
| Bellevue | 2—4500 kv-a. | 10 |
| Lamokin | 2—4500 kv-a. | 10 |
| Glenolden | 2—4500 kv-a. | 8 |
| Arsenal Bridge | 2—4500 kv-a. | 9 |
| Morton | 2—4500 kv-a. | 4 |
| Lenni | 2—4500 kv-a. | 3 |
| Cheyney | 1—4500 kv-a. | 1 |
| West Chester | 2—4500 kv-a. | 1 |

The average interval between substations is 6.4 mi.

It is planned that the number of step-down transformers in each of the substations serving the main line may ultimately be increased to four.

The transformers are self-cooling, and are capable of carrying continuous rated load, followed by 150 per cent of rated load for two hours, followed by 300 per cent of rated load for five minutes.

A schematic diagram of one of the substations, indicating the arrangement of connections, is shown on Fig. 7.

A feature of these substations, as well as of the step-up substation, is the absence of oil circuit breakers in the high tension side.

In the step-up substation oil circuit breakers are provided in the low tension side of the transformers, giving automatic protection in the event of transmission line fault. The transformers are connected on the high tension side to outgoing transmission lines through two-pole 132-kv. air sectionalizing switches, remote electrically controlled, which are not to be opened under load, but are capable of interrupting transformer exciting current.

In a similar manner the transformers in each of the step-down substations are connected to the high-tension lines through air sectionalizing switches, and the low tension side of each is connected to trolley and rail buses through a two-pole oil circuit breaker, arranged for automatic tripping on reverse power, on unbalanced voltage on the high tension side, or by differential protection against failure on the trolley bus or within the transformer. A fault on any part of a 132-kv. transmission circuit will trip out of service one transformer in the step-up station and one transformer in each step-down station which is served by the transmission line on which the fault occurs. Such an outage does not affect train operation, as sufficient transformer capacity remains in each substation to handle maximum expected loads. If the transmission line fault is to ground only, and does not involve the opposite conductor, the flow of current through the earth, back to the step-up station is limited to about 200 amperes by a neutral resistance connected to the mid-point of each step-up transformer.

FIG. 7—SCHEMATIC DIAGRAM—BELLEVUE SUBSTATION

**Pennsylvania Railroad—Philadelphia Suburban Electrification**

Trolleys are sectionalized at each substation and each trolley section is normally fed from each end, thereby avoiding "stub-end feed." Trolley circuit breakers are designed to open under short circuit within an interval of time not exceeding 1/25 sec. The rupturing capacity of these circuit breakers is 50,000 amperes. This high value of rupturing capacity was required with a view to ultimate conditions as to transformer capacity at step-up and step-down substations. This installation represents the first use on any extensive scale of quick opening circuit breakers in a-c. railway electrification, and it is expected that inductive disturbances and damage to overhead wires and insulators resulting from trolley short circuits will be minimized by the quick acting feature.

At each substation there is provided a small building to house a control storage battery and charging equipment, protective relays and oil conditioning apparatus. All other equipment is of outdoor type.

Substations are unattended, and are controlled from a panel containing control switches and indicating lamps placed in signal interlocking towers or other points continuously attended. Certain substations on the West Chester branch are so remote from a continuously attended tower that it was necessary to provide supervisory control for these substations, utilizing wire circuits in an aerial communication cable along the right-of-way.

*Contact System.* The contact system for all main running tracks comprises a 4/0 bronze contact wire, 40 per cent conductivity referred to copper, reinforced by a 4/0 copper auxiliary, supported by a 19-strand bronze messenger ⅝ in. diameter, of high strength and relatively low conductivity. No paralleling feeders were required. In yard construction the copper auxiliary is omitted.

*Track Return.* All rail joints on main track are double bonded, not for conductivity but to minimize signal failure due to broken bonds. A major portion of the trackage is bonded with No. 1 bonds, gas welded to the head of the rail, and on the remainder of the work No. 1/0 bonds with expanded pin terminals are used, installed where possible under the joint plates. Cross bonds of two No. 2/0 copper are installed at intervals to cross-connect the mid-points of impedance bonds.

The type of system of transmission, conversion, and distribution adopted for the Philadelphia-Wilmington electrification gives a high degree of selectivity in the automatic tripping of circuit breakers in the event of short circuits, and is adaptable to future extensions over considerable distances and to such increase in installed capacity as will be required for the future operation of through freight and passenger traffic. The West Chester line was equipped in a manner similar to the Philadelphia-Wilmington line, partly for the sake of uniformity of apparatus, and partly because the 132 kv. transmission lines will ultimately be used as a part of a transmission network, in connection with future extensions of the electrification on the main line to the West, and elsewhere.

## Discussion

For discussion of this paper see page 1311.

# Protection of Electric Locomotives and Cars
## to Operate with High-Speed Circuit Breakers

BY E. H. BROWN[1]
Non-member

***Synopsis.**—This paper discusses the requirements for protecting the high-tension circuits of an electric car or locomotive which operates on the a-c. single-phase system of electrification.*

*The means which must be employed to secure this protection is outlined. The types of relays used by the Pennsylvania Railroad for this purpose are described, together with the connected control circuits. These relays are known as pantograph lowering relays, and they make use of the opening of the substation breakers on a short circuit to disconnect the electrical equipment of the car or locomotive from the line by lowering the pantograph. Tests of high-speed relays recently developed indicate that these relays will give satisfactory service with high-speed circuit breakers in the trolley feeders at the substations.*

*In conclusion, results justify the elimination of circuit breakers from electric cars and locomotives by the substitution of the pantograph lowering relay.*

THE protection of the electrical equipment of an electric car or locomotive utilizing the a-c. single-phase system may be divided into two general problems:

1. Protection of the high-tension circuits and the transformer from damage due to grounds or short circuits.
2. The protection of the motors and their connecting low-tension circuits.

While the problems are associated, we will, for the purpose of this paper, consider only the problem involved in protecting the transformer and high-tension circuits from the results of short circuits, as transformer overload due to the operation of the motors will be taken care of by the operation of the overload devices in the motor circuits.

It was formerly the general practise, and this practise is still followed on many railroads using the single-phase system, to protect the transformer and the high-tension wiring by an oil circuit breaker of adequate capacity installed on the car or locomotive. On the Pennsylvania railroad, however, a somewhat different practise has been developed for the a-c. multiple unit car and locomotive equipment, as it has been found difficult to provide, in the space available on the cars or locomotives, an oil switch of a capacity adequate to open the high currents which are possible upon short circuit under our operating conditions. This practise is, in brief, to insert, between the pantograph and the transformer, a device known as a pantograph lowering relay, which makes use of the substation circuit breakers feeding the trolley wire instead of an oil circuit breaker on the locomotive or car. The method followed in the apparatus used is as given below:

In the circuit between the pantograph and the transformer is inserted a relay known as the pantograph lowering relay. When an excessive current passes through this circuit, the pantograph lowering relay initiates the operation of lowering the pantograph through the control circuits and electropneumatic operating devices. This operation cannot be completed until the opening of the substation breaker. The consequent removal of current from the pantograph and its connected circuit permits the relay to complete its operation which closes the control circuit to the pantograph lowering device and lowers the pantograph during the time that the substation breaker is out. It can readily be seen that this device must accomplish three things:

1. It must initiate the lowering operation prior to the opening of the substation breaker, because it depends on the excessive current flowing in the circuit to do so.
2. It must not complete this operation until after the substation breaker has opened, as it would be highly undesirable to attempt to interrupt the current flow by lowering the pantograph with the resultant possibility of severing the overhead contact wire by a power arc.
3. It must lower the pantograph in the interval between the time of opening of the substation breaker and the closing of this breaker by the substation operator.

Other features of the device are important and these will be dealt with in the following paragraphs:

It may readily be seen that after the device has functioned to lower the pantograph on a car or locomotive upon which the equipment is defective, the pantograph should not be raised by the ordinary means at the motorman's command. An interlocking must be provided at the pantograph lowering relay to prevent raising of the pantograph by the usual control methods.

It is also necessary that the pantograph lowering relay shall assure, as far as possible, that the pantograph on the car or locomotive, upon which the equipment is defective, shall remain lowered even though the latching device may fail and consequently means should be provided to retain the air in the lowering cylinders, thus preventing raising of the pantograph, even should the locking device fail.

The principal requirements will now be considered in detail, to point out the manner in which each affects the design of the relay. The first requirement, that the

---

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

relay initiate the lowering operation before the substation breaker opens, is by far the most important. It is fundamental and upon the success of this first operation depends the whole sequence of the further events. When the use of the high-speed substation breaker was decided upon for the Philadelphia-to-Wilmington and the West Chester electrifications of the Pennsylvania Railroad, preliminary laboratory experiments demonstrated that the type of pantograph lowering relay which had previously been used would not operate with this type of breaker. While these relays had been satisfactory with the lower speed of operation of breakers in the existing substations, the high-speed breaker opening the short circuit as rapidly as one-half a normal cycle on 25-cycle current, would not permit a sufficient impulse to be received by the relay before power was off the line. It therefore became necessary to develop new relays requiring less energy input, but operating on the same current values as before. These newly developed types will shortly be described.

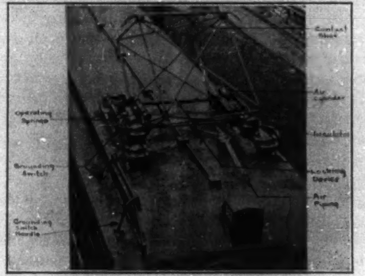

Fig. 1—Multiple Unit Car Pantograph

The second requirement for the relay is that it must not complete the operation of lowering the pantograph until the substation breaker is opened. This is an important function, but one which, with quick acting breakers especially, will seldom be called into effect. There is one condition, however, which makes this requirement most important. This condition exists when a short circuit occurs of sufficient value to trip the pantograph lowering relay, but does not operate the substation breaker immediately. The pantograph in this case must not be lowered until the short circuit has reached a sufficient value to trip the substation breaker and remove power from the line. This function can be accomplished by means of an electrical interlock breaking the pantograph lowering circuit as long as the relay is energized by the short circuit current.

The third requirement is that the relay must lower the pantograph before the substation breaker is reclosed. This is not difficult to meet. Under usual operating conditions, when a substation breaker opens upon short circuit, approximately one minute will elapse before the substation operator has received instructions from the qualified supervisor and has reclosed the breaker. Since lowering the pantograph requires a time of only about one second, this can readily be accomplished.

The lowering operation, nevertheless, must be an automatic function of the relay and must be performed without unnecessary delay.

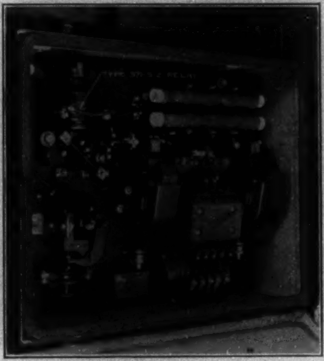

Fig. 2—Type 371S2 Pantograph Lowering Relay

Standard type in service on the Philadelphia-Paoli electrification

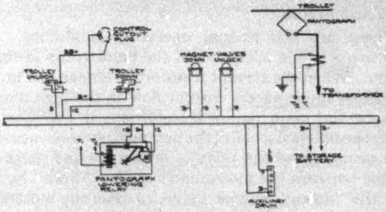

Fig. 3—Diagram of Pantograph Control Circuits Using Type 371S2 Pantograph Lowering Relay

A description of the various types of relays employed for lowering the pantograph will bring out the means by which the above outlined requirements have been accomplished.

First, we will consider the relay and its connecting circuits now in service on the Philadelphia-to-Paoli electrification of the Pennsylvania Railroad. This relay is known as "Type 371S2." Fig. 3 illustrates diagrammatically the electrical control affecting this relay and the pantograph. The pantograph is in its normal operating position. The auxiliary, or sequence drum, by which the motor switches are controlled, is in the "off" position, indicating that the motor switches are open. The pantograph may now be lowered by pressing the trolley "down" button, admitting air to the lowering cylinders on the pantograph. It will be noted, however, that by means of the 12 and 19 wires, this operation is so interlocked that it cannot be performed when the circuit has been opened by energizing the pantograph lowering relay. This gives the necessary protection to prevent the pantograph from being lowered during a short circuit. When the pantograph has been lowered, it is automatically latched by a mechanical device. It can be unlatched by pressing the trolley "unlock" button. The operating springs will then raise it to the contact wire. This operation is interlocked electrically in two places. First, the control cut-out plug must be placed in its proper receptacle by the motorman, and second, the auxiliary drum must be in its "off" position, so that the motors are disconnected.

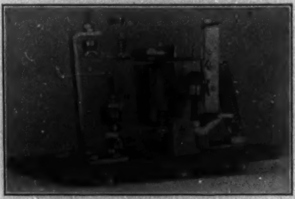

Fig. 4—Type UC-8 Pantograph Lowering Relay

These are the normal operating conditions. We now come to the operation of the pantograph lowering relay. When the current transformer shown on Fig. 3 is energized by an excess current flow in the high tension lead to the main power transformer, it energizes, in turn, the operating coil of the pantograph lowering relay. The armature of the relay is drawn up and parts the circuit between the motorman's trolley "down" button and the "down" magnet valve, so that the motorman cannot lower the pantograph and the circuit is held open for the duration of the short circuit. As soon as power goes off the trolley, by opening of the substation breaker, the operating coil of the relay is deenergized. In the meantime, the contact bearing member has been rotated by means of a spring, so that, when the armature falls back, it closes the circuit to the battery and applies current to the "down" magnet valve, thus lowering the pantograph. This supplies the automatic lowering operation of requirement No. 3, before mentioned.

When the "down" magnet valve has been energized by operation of the pantograph lowering relay, it is connected directly to the battery and remains energized. Thus air pressure is held in the pantograph lowering cylinders as long as it is available in the control air reservoirs. By this means the trolley is held down, regardless of the failure of the latching device and also regardless of an effort to raise it with the motorman's "unlock" button.

Resetting of a relay by members of the train crew is not permitted. A car on which the pantograph has been lowered by the operation of this relay, and which does not respond to the "unlock" button, is towed by the other cars in the train until such time as it can be inspected by members of the shop force, in order to determine the cause of the lowering operation.

Relays, as above described, using an electromagnet operated by current from a current transformer in the main high-tension lead and having a movable iron armature, have been in satisfactory operation up to the present time, but have proved unsatisfactory for use with high-speed breakers. A new design of this same type has recently been produced that has not yet demonstrated its ability to operate at the required speed.

To take the place of these relays, two different types have been submitted. One is operated directly by the magnetic effect of the power current passing through a surrounding iron core and eliminating both current transformer and relay operating coil. The other type utilizes current from the current transformer to operate a solenoid and plunger instead of the electromagnet and armature. Both of these devices have demonstrated, by means of oscillograph tests, that they will perform satisfactorily with short circuit current flowing in the trolley circuit for less than one-half cycle.

Reference to Fig. 5 will show the circuit arrangement for the first of these high-speed relays. This relay is known as "Type UC-8." It is composed of a rectangular magnetic core surrounding the high-tension lead, one leg of which core is pivoted along its length (see Fig. 4). This leg is slightly tilted under normal conditions to give a small air-gap. Current flow in the high-tension cable magnetizes the core, tending to close the air-gap. By means of contacts mounted on the movable leg, the same circuit relations are obtained with this relay as with the old type of relay. By the use of a laminated magnetic circuit and moving parts of low moment of inertia, it has been possible to design this relay to operate within approximately

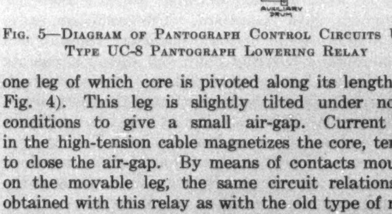

Fig. 5—Diagram of Pantograph Control Circuits Using Type UC-8 Pantograph Lowering Relay

one-third of a cycle. A typical oscillogram of this relay is shown in Fig. 6.

The second type of high-speed relay is shown in Fig. 7. It is operated by means of a solenoid plunger and is shown in conjunction with a different type of pantograph control, utilizing only one magnet valve (see Fig. 8). The magnet valve admits air to a cylinder at the pantograph, the piston of which cylinder opposes the action of holding-down springs and permits the operating springs to raise the pantograph. When air is released from the cylinder by deenergizing the magnet valve, the holding-down springs lower the pantograph. These springs are so interlinked that they overcome the raising action of the operating springs and hold down the pantograph without the necessity of an additional latching device.

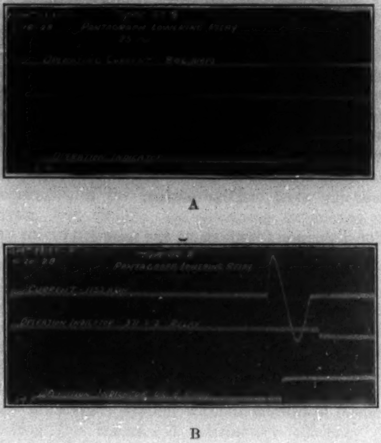

Fig. 6—Typical Oscillograms of Type UC-8 and Type 37182 Relays

a. The upper line indicates trolley current. Note that the current was flowing during only one half a cycle

The middle line traces a circuit indicating the operation of a type 37182 relay. The fact that this line is unbroken indicates that the relay did not function

The lower line is traced by a circuit through the contacts of a type UC-8 relay. The relay has operated well within the one-half cycle

b. The current flow lasted for a full cycle in this test

The type 37182 relay received sufficient impulse this time to operate. The contacts of the relay, however, did not part until after power was off the trolley

The type UC-8 relay again operated within one half cycle

An additional relay is necessary with the type of control just described. This relay is called the pantograph operating relay. The function of this relay is to hold open the magnet valve which maintains the pantograph in its extended position, against the contact wire, during normal operation.

By referring again to Fig. 8 it will be seen that, in order to keep the pantograph in its operating position, the 21 wire leading to the magnet valve must be energized and thus the pantograph operating relay must be in its latched position, as shown by the diagram. This is done by energizing the lower solenoid of the relay by means of the trolley "up" button. This push-button circuit is interlocked, as with the previously described pantograph operating circuit, so that the control cutout plug must be in place and the auxiliary drum must be in the "off" position. It is also interlocked with the pantograph lowering relay, so that the operating relay cannot be energized when the lowering relay has been tripped.

Fig. 7—Solenoid Type of Pantograph Lowering Relay

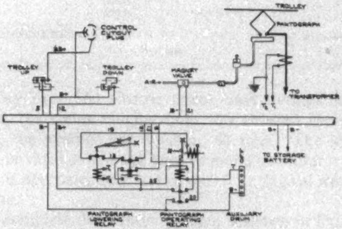

Fig. 8—Diagram of Pantograph Control Circuits Using Solenoid Type of Pantograph Lowering Relay

The normal lowering operation is performed by energizing the upper or tripping solenoid of the operating relay which trips the latch and breaks the circuit from the magnet valve wire No. 21 to the battery. Operation of the tripping solenoid is interlocked with the pantograph lowering relay, so that when the solenoid of this latter named relay is energized the circuit to the tripping coil is broken and is not closed until the pantograph lowering relay is deenergized and the 19 wire is reconnected to the 13 wire. It can be seen that, when the lowering relay is tripped, this 13 wire is connected directly to the battery and trips the operating relay immediately upon removal of short circuit current from the trolley by the substation breaker. An oscillogram showing a typical operation of this relay is given in Fig. 9.

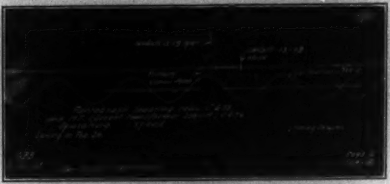

Fig. 9—Typical Oscillogram of Solenoid Type of Pantograph Lowering Relay

This type of relay has given satisfactory test results with currents from 500 amperes upward flowing for one half cycle

This oscillogram indicates successful operation with 1930 amperes flowing for 0.3 cycles on the basis of 25 cycles per sec.

In conclusion, results secured in the past with pantograph lowering relays have been satisfactory. There have been no indications that the relays have failed to function when required. Although in numerous instances the relays have operated without proper cause, these false operations have been largely eliminated by improved design and proper setting of the relay. Recently, types have been developed which are more positive in action and are less susceptible to vibration, and they have been made sufficiently sensitive and rapid in operation to be used with high-speed substation breakers.

It is felt that the additional investment required and the effort necessary to provide space on locomotives and cars for circuit breakers of proper size is unwarranted, and that such breakers may be eliminated by the installation of a pantograph lowering relay making use of the opening of the substation breaker to disconnect the electrical equipment of the car or locomotive from the line by lowering the pantograph.

## Discussion

For discussion of this paper see page 1311.

# The High-Speed Circuit Breaker in Service
## on the Illinois Central Railroad

BY W. P. MONROE[1] Member, A. I. E. E. and R. M. ALLEN[2] Non-member

***Synopsis.**—The purpose of this paper is to describe briefly the distribution system of the Illinois Central Suburban Electrification and to state considerations influencing the selection of high-speed circuit breakers for d-c. feeder and machine protection. The knowledge gained by nearly two years' operating experience with this system, which contains 98 high-speed circuit breakers, and the conclusions reached, are also presented.*

* * * * *

THE first large installation of high-voltage d-c. high-speed circuit breakers for railway service was placed in operation on the Chicago suburban electrification of the Illinois Central Railroad, in July, 1926. The reasons for the adoption of these circuit breakers for this electrification, and the results thus far obtained with them, may be of interest to those who are contemplating similar applications. With this idea in mind, the distribution system in general will first be described with special regard to those features influencing the selection of the high-speed breakers. A description of the installation and tests will then be given, and finally, the operating experience of twenty months service will be discussed.

### DESIGN FEATURES OF DISTRIBUTION SYSTEM[3]

The distribution system of this 1500-volt d-c. suburban electrification was designed to deliver current to the trains with the necessary voltage regulation, with economy in the use of copper, and with the utmost reliability. A simple system resulted consisting of seven substations conveniently spaced and feeding directly a catenary system without additional feeders paralleling the tracks. A satisfactory efficiency of distribution was obtained by the use of *tie stations* to connect the catenaries of all tracks together at various points, thus dividing the current among the catenaries over all tracks and utilizing the total copper to the best advantage.

The absence of feeders, other than the catenaries themselves and the substation connections thereto, is a factor in obtaining simplicity and in applying high-speed circuit breakers. It happened that the mechanical design of the catenary was very well suited to the conductivity requirements, this feature being partly due to the use of tie stations and partly due to the fairly close spacing of the substations.

The tie stations, besides increasing the distribution efficiency, divide the catenary system into short sections, each fed through its own circuit breakers. Because of the large number of sections and sectionalizing points of this design, remote control of the circuit breakers is necessary. The Illinois Central system makes use of supervisory control by which the power supervisor, from his desk, can open or close any circuit breaker on the system and receive indications of the opened or closed positions of these breakers at any time.

A simplified schematic diagram of the distribution system in the district having the heaviest traffic is shown in Fig. 1. It is of that portion of the system extending from the north terminus at Randolph Street to Brookdale Substation, 8.3 miles south. On every week-day over 560 electric trains pass through this district, the trains ranging from two to eight cars in length, the average car weighing 63 tons. The load factor, or ratio of average hour to maximum hour over 24 hr., is approximately 40 per cent for a typical week-day load.

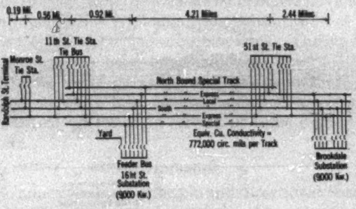

FIG. 1—SCHEMATIC DIAGRAM OF PORTION OF DISTRIBUTION SYSTEM

The complete distribution system is shown in Fig. 2.

### CONSIDERATIONS LEADING TO THE SELECTION OF HIGH-SPEED BREAKERS FOR THE SERVICE

The reliability of the distribution system depends upon adequate protection from short circuits, overloads, and other electrical disturbances. Its availability, or freedom from service interruptions, depends upon the quick isolation from the rest of the system of a section directly affected by the fault without interfering with service on the neighboring sections.

An inspection of Fig. 1 shows that in the Illinois

[3] For a detailed description of the I. C. R. R. distribution system and other phases of this electrification, see series of articles in *General Electric Review*, April, 1927.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

Central distribution system most of the sections of track are fed directly or indirectly through a large number of circuit breakers; and that if a short circuit occurs in one section, a number of other sections may be affected unless only the breakers feeding directly into the short circuited section open and isolate it. The circuit breakers, therefore, should have a high degree of selectivity in their operation.

They should also act at sufficiently high-speed to avoid serious burning of the catenary or train equipment.

FIG. 2—COMPLETE SCHEME OF DISTRIBUTION ON THE ILLINOIS CENTRAL RAILROAD

They should be adapted to remote control since many of them will be in unattended stations and all must be under direct control of the power supervisor's office.

Their reliability should be such that they will not require very frequent maintenance attention.

The Commonwealth Edison Company of Chicago and affiliated Public Service Company of Northern Illinois own and operate the substations feeding the Illinois Central distribution system, and also own and maintain the feeder circuit breakers in the substations. The operation of these breakers, however, is of great importance to the railroad because they form a part of the distribution system and must act in conjunction with the tie station breakers. The Edison Company and railroad engineers, therefore, worked together in selecting the type of circuit breaker and protection scheme used in the substations.

A study of the merits of all proposed 1500-volt d-c. circuit breakers, including extensive factory tests, resulted in the selection of the General Electric type J R high-speed circuit breaker for the service, and this type is used in all section feeders at all substations and tie stations (Fig. 3). They are also used in both positive and negative leads of the synchronous converters in substations. The detailed theory of action of this breaker has been previously described before the Institute.[4]

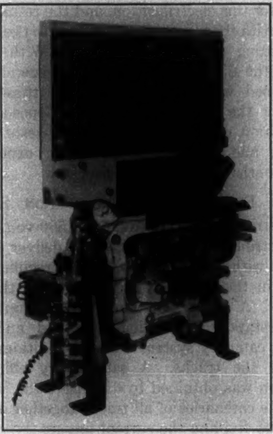

FIG. 3—HIGH-SPEED BREAKER UNMOUNTED

## INSTALLATION AND INAUGURATION OF SERVICE

The most modern type of construction was used in the installation of the circuit breakers in both substations and tie stations. Each high-speed breaker is mounted on its own truck with control panel, and spare trucks with breakers are available so that repairing is made easy by the removal of the bad order circuit breaker and truck to be repaired and replacing it with a spare truck containing a spare circuit breaker. The circuit breaker trucks can be interchanged readily in the tie stations and in the substations, but an attempt is made always to keep each breaker in the same feeder. Although most of the parts are interchangeable, a complete tie station breaker cannot be interchanged with a substation breaker, because the holding coil of the tie station breaker is energized from 1500 volts while that of the substation breaker is energized from the substation 125-volt d-c. supply.

---

[4] *The High-Speed Circuit Breaker in Railway Feeder Networks*, by J. W. McNairy, TRANS. A. I. E. E., Vol. XLV, 1926, p. 962.

Automatic reclosing features are a part of the control of the tie station breakers, but the closing of substation feeder breakers is governed entirely by supervisory control. Both tie stations and substations are equipped with transfer buses so that in emergencies two or more sections can be fed through the same circuit breaker.

The calibration of the feeder circuit breakers was made at the factory. The settings of the tripping points, however, were precalculated by the railroad company's engineers, and the breakers were set accordingly during the installation. In order to make sure that the predetermined settings were right, a number of short circuit tests was made at the completion of the installation and when power was available at the d-c. buses of the substations. A test car was equipped so that short circuits could be applied at any point, and an oscillograph was installed in the car to record the short-circuit currents and time characteristics of the circuit breakers.

The first tests were made at the Homewood tie station, in an outlying district, where short circuits were applied to the catenary at a point very close to the tie station. It was found that the selectivity of the circuit breakers in isolating the fault was very satisfactory. Tests were also made at 11th Street tie station, one of the largest tie stations in the system, and in this case also the selectivity was satisfactory with the predetermined settings, but some minor adjustments were found to be necessary. Similar tests were made at the other tie stations and substations. In this way the system was "tuned up" for safe and correct operation of circuit breakers. In only a few cases was it deemed advisable to change the predetermined circuit breaker settings.

In the two-track district between Front Avenue and Harvey substations, there is no tie station, (see Fig. 2). It was found that the rate of current rise at one of the Front Avenue substation feeder breakers was not sufficient to open it when a short circuit was applied near the Harvey substation, although the Harvey substation end cleared satisfactorily. The short-circuit current in this case is limited to a maximum value of approximately 3500 amperes by the resistance of the line. The predetermined setting of the Front Avenue breakers was 4000 amperes, but it had to be reduced to 3500 amperes to insure protection. Since the breakers feeding the district south from Brookdale substation to Front Avenue substation, and those feeding north from Harvey substation to Front Avenue have the same feeding distance without tie stations, their settings were also lowered to 3500 amperes. Later, the manufacturers altered the design of the inductive shunt for these breakers, changing both resistance and inductance, so that the settings could be raised to 4000 amperes with ample protection. These circuit breakers with low settings are now all equipped with the new shunts and the settings readjusted to 4000 amperes accordingly. Since the accelerating current of a ten-car multiple unit train approaches 4000 amperes the setting at 4000 amperes (for straight overload) seems to be low to prevent circuit breaker openings from the useful load. Actually, the breakers are sometimes opened by the load, and as traffic increases, the openings will increase. It has always been the intention of the railroad to build a tie station in each of these districts when the traffic so demands.

These preliminary tests on the distribution system have proved the advisability, if not the necessity, of thoroughly trying out a distribution system of this kind before regular service is started. As a further precaution, when the I. C. R. R. electric suburban service was fully inaugurated in August, 1926, emergency operators were stationed in the most important tie stations during the rush hours to take care of any failure or faulty operation of the circuit breakers. The necessity for this latter precaution was not proved, however, since no serious troubles developed.

## RESULTS OF TWENTY MONTHS OPERATING EXPERIENCE

Since August 1926, the high-speed breakers have been in continuous service handling the dense traffic of the Illinois Central electrified suburban lines. During this period, there has been opportunity to observe their performance under varying conditions, and there are presented herewith brief comments on certain features of the actual operation in service of these high-speed breakers.

### ADVANTAGES

The inductive shunt principle and directional characteristics of the high-speed circuit breakers make automatic isolation of trouble by selective operation simple and almost 100 per cent.

The high-speed operation reduces to a minimum the damage to train equipment and overhead. In fact, the burning is so slight that in most cases it is difficult to locate by inspection a traction motor which has flashed over. In no case has the damage by a single flashover been sufficient to necessitate taking a motor out of service.

With a lapping section insulator, such as is used on the Illinois Central, more or less burning is caused by a pantograph moving over a section insulator, one side of which is alive and the other side temporarily grounded by a short circuit or for some other reason. High-speed circuit breakers reduce this burning to a minimum. A recent communication from the Victorian Railways of Melbourne, Australia, which is in the process of changing to high-speed circuit breakers on their 1500-volt d-c. electrification, states that trouble from this cause has been considerably reduced thereby. Their report bears out the experience of the Illinois Central.

Care of the high-speed circuit breaker contracts has been found to be almost unnecessary, due to the secure manner in which they are held together magnetically, instead of relying on a spring and latch arrangement.

In the early stages of electric operation, there was a very large number of automatic circuit breaker openings for which there was no visible cause. Many of these were due to overhead or train equipment troubles which occurred periodically and the small amount of burning made it impossible to locate the fault by ordinary inspection. Others were known to be due to motor flashovers caused by wheels slipping on wet rails; this is now avoided by proper handling of the trains by motormen.

To trace recurring troubles, a systematic record of automatic circuit breaker openings is kept. For each automatic opening a notation is made in this record of the train in the trolley section, the numbers of the motor cars in the train, location of the train, and the name of the motorman. The following results were and are obtained from the study of periodic summaries of this information:

1. Motor flashovers due to slipping of wheels was confined to a few motormen. These motormen were given special instructions and motor flashovers from this cause have been reduced from about thirty per month to about three per month, and the damage is almost negligible.

2. If an unusual number of circuit breaker openings is found to occur at times when trains are passing a certain point, a thorough inspection of the overhead is made, which usually results in the discovery of a catenary defect at the location.

3. Car equipment trouble is shown by an excess of circuit breaker openings marked against a particular car and this car is taken in for inspection. These inspections invariably verify the evidence shown by the automatic opening report.

It is believed the tracing of these faults before serious damage results is made possible by the high speed characteristics of the circuit breakers.

### DISADVANTAGES

There is theoretically an inherent defect in the high-speed breaker characteristics as applied in this service with a short circuit occurring at the time of heavy traction load. When the circuit breaker is carrying heavy current in the right direction for its operation and a short circuit occurs on an adjacent section not directly fed by the breaker, there is a possibility of the breaker opening automatically and incorrectly from the selectivity standpoint. This incorrect operation is due to the load current superimposed on the short-circuit current, the effect being to lower the critical rate of current increase which will open the breaker on short circuit. Actually there have been very few incorrect automatic openings of circuit breakers which have been traced to this cause.

The setting of high-speed circuit breakers on the Illinois Central is accomplished by turning a one-inch iron screw in or out of the holding coil core, thus varying the reluctance of the holding coil magnetic circuit. A marked brass calibrating plate serves as a scale. Such a method of setting is not very accurate considering that highly selective operation is expected. Also, a circuit breaker truck must be removed from the circuit in order to change the setting.

The breaker setting is changed somewhat by the wearing of the main contacts, and periodic calibrating will probably be necessary. Such calibration would require artificial loading which would be cumbersome with 5000- or 6000-ampere settings. However, this will be an infrequent procedure.

Although its advisability may be questioned, it is a practise of most operating companies to relieve traffic congestions by holding carbon circuit breakers closed for a short time. The high-speed circuit breaker does not permit this practise and three cases of breakers opening on legitimate load on the Illinois Central have resulted in serious delays.

It is sometimes desirable to burn clear a minor short circuit. This is almost impossible due to the high-speed operation. In one case, a No. 12 A. W. G. meter lead grounded to the meter frame and could not be burned clear. This occurred on a test train previous to regular operation, but could have caused serious delays had it occurred in regular service, since it was difficult to locate.

The injurious effects of the high-voltage surges induced by the high-speed operation have sometimes been cited as a disadvantage of the device. These surges on our system amount to approximately double the line voltage and are greater than the surges due to openings of carbon circuit breakers. There has been no direct evidence of damage caused by these surges on the Illinois Central.

A number of minor changes in design of the high-speed breakers has been effected since the original installation. These alterations were made by the manufacturers to correct faults which developed under operating conditions. As an example, considerable trouble was experienced by the breakers pumping, due apparently to bouncing of the armature against the core. This pumping often resulted in the reset coil burning out. A change in design of the reset coil core has corrected this defect.

The reset coils of the present high-speed breakers seem to be designed with only a narrow margin of safety as regards operating temperature, since they will reach dangerous temperatures if operated at too frequent intervals. A more liberal design of coil would correct this disadvantage.

Two serious substation bus short circuits were experienced, which may have been due to insufficient clearance of the sheet metal enclosure of the breaker mechanism. The circuit breakers are now being mounted on an ebony asbestos base, instead of metal, and no further trouble is expected. It is understood the manufacturer is incorporating this change of design in all new high-speed circuit breakers.

It was necessary to raise the overload setting and to remove all but $\frac{3}{8}$ in. of the iron on the inductive shunt of the positive machine breaker in the substations, which was set for a low value of reverse current. A sudden interruption of current in the normal direction (such as opening of a feeder breaker) causes a reverse flow of current in the bucking bar due to the collapse of magnetic flux in the inductive shunt, the effect being to open the breaker unnecessarily. The changes in the setting and inductance of the shunt obviate this difficulty.

It is concluded that the disadvantages in this case may be said to be minor defects and there is no doubt that the high speed breaker has contributed much to the success of the Illinois Central electrification.

---

## Discussion

### PAPERS ON ELECTRIFIED RAILWAYS

(McNairy, Wilcox, Bardo, Morton, Brown, Monroe and Allen)

Denver, Colo., June 27, 1928

**H. C. Graves:** Mr. Wilcox mentions selective relaying equipment as a necessary adjunct to the breaker described in the paper presented by him. I should like to outline the system conditions obtaining on an actual, typical system, which made simple over-current tripping means inadequate, to describe the application of high-speed relays, and to give test results which illustrate the adequacy of the protective relay equipment used.

The four-track railway system connection is shown at the bottom of the accompanying Fig. 1. The four 11-kv. contact lines are sectionalized at each feed-in substation, which are located at approximately equal intervals. Each 11-kv. substation bus is fed by high-tension feeders through one to four transformers depending on load conditions. The generating capacity feeding into the high-tension feeders through transformers, may vary from one to eight generators. The impedance of the high-tension feeders is negligible as compared to the impedance of generators, transformers, and contact lines.

Short-circuit conditions existing on this system are as shown at the top of Fig. 1. Since the high-speed relays must operate within 0.01 sec., or $\frac{1}{4}$ of the cycle, after the relay setting is exceeded, they must frequently operate under asymmetrical current conditions. For this reason, the maximum current condition which must be considered is the maximum instantaneous asymmetrical condition. These maximum values of current which operate the relay on the faulty line, for example at bus *A* in Fig. 1, are shown in Curve 1 ranging from 24,000 amperes with a fault located just outside of the breaker near the bus to 2700 amperes when the fault is at the opposite end of the line. Minimum values of fault currents will exist when the fault occurs at a time which causes symmetrical conditions of current to exist, and when the generating capacity is a minimum. These currents are as shown by Curve 2. The ratio between maximum fault currents to minimum currents with all breakers closed is seen to be approximately 6 to 1.

During fault conditions, some currents will flow in unfaulted contact lines and tend to cause operation of their protective relays. Curve 3 shows how these currents vary for a particular operating setup. Under these conditions the line relays must not cause tripping.

Using these curves as a basis for determining the type and setting of protective relays it may be seen that instantaneous over-current relays cannot be applied to protect against all conditions because: (1) Under minimum operating conditions they must clear with 1700 amperes flowing into each end of the line, the fault being in the middle; or if the fault occurs at one end of the line the breakers must clear with 4200 amperes flowing at that end but only 600 amperes flowing at the other end. This is shown in Curve 2. (2) Under certain conditions, as shown in Curve 3, 2700 amperes may flow in the unfaulted line which must not cause clearing. If the relays do operate under this condition, a total of 16 breakers may open, two of these alone being sufficient to clear the faulty line. (3) To the fault current in the unfaulted line may be added load current of 1200 amperes which still must not cause clearing.

Thus the relay system must operate with only 600 amperes flowing in a faulted line and must not operate with 3900 amperes flowing in an unfaulted line in order to assure perfect selectivity. Further calculations also show that with a fault near one end of the line, the breaker nearest the fault being open, the current flow through the other end may be only 1900 amperes and the relay must operate under this condition. Simple over-current relays are obviously not applicable.

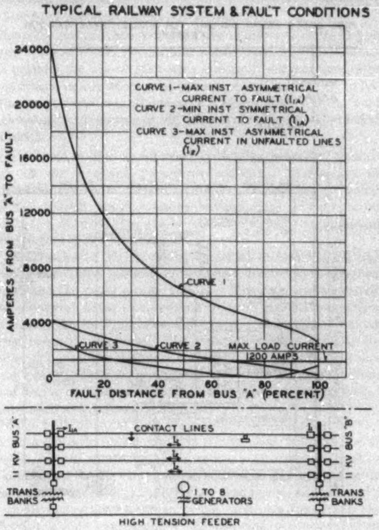

Fig. 1

In order to secure all the advantages of the high-speed breakers, cascading or sequential operation of breakers should be avoided. This is a function of the relay system.

One suitable system of protection could be built around pilot wires. An objection to this system is found in the cost and maintenance. A second suitable system involves installing reactors in series with each breaker so that the current in the faulty line is always larger than that in the unfaulted lines. The reactors create an unbalanced current so that even with the fault just outside of the bus, relays can be made to discriminate on the unbalance. The objection to this system lies in the cost and increased voltage drop and losses due to the line reactors.

In either of the above systems provision must be made for suitable compensation for normal load currents.

A relatively inexpensive scheme of protection has been devised to give 100 per cent selectivity which permits cascading for only a very small percentage of the contact line length. It does not necessitate line reactors or pilot wires, and works from standard current and potential transformers. The relays operate in from 0.001 to less than 0.01 sec. from the time when the relay setting is exceeded.

The scheme is built about a relay which is independent of connected generating capacity. This is an over-current relay, instantaneous in its operation, which has a current setting dependent on the bus voltage. With a fault located at a definite point on a contact line, the ratio between voltage and current, which determines the operating point of this relay, is a constant. Thus the relay is equivalent to an impedance-measuring device and can therefore be set to operate for any faults within a certain distance from the breaker. The sensitivity of this relay is such that in practise, it is set to operate with faults located within 90 to 95 per cent of the contact-line length.

HIGH SPEED RELAY SCHEME FOR SINGLE PHASE RAILWAY FEEDERS

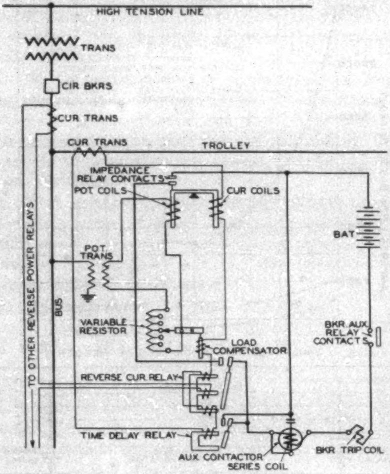

FIG. 2

With faults near one end of the line, the current through the other end of the line will be small, and will correspond to approximately 600 amperes or one-half of the maximum normal load current. However, the voltage on the relay at the far end is low so that the relay will operate. Thus this device will not operate on 1200-ampere load current but will operate on a 600-ampere fault current or even less.

When a load is connected just outside of one breaker, it will effectively change the impedance of the line when faults occur at the opposite end of the line. Its effect is to reduce the impedance to the flow of current through the breaker and thus increase the likelihood of the relay operation. Therefore, in order to avoid faulty operation a presetting device has been added which changes the impedance setting of the relay depending upon the amount of load in the circuit. The diagram in Fig. 2 shows how this setting change is effected. The load presetting relay cuts out resistance, normally in series with the potential restraining circuit of the impedance relay, as the current in the line increases. Thus when loads are located on this line near the station the effect of the potential coil is comparatively large. As this load travels along the contact line toward the other station the load presetting relay slowly changes the amount of resistance in series with the potential coil so that the relay will always operate, independently of load conditions, with all faults located within 90 to 95 per cent of the distance to the next substation.

INSTANTANEOUS DIRECTIONAL RELAY CHARACTERISTIC

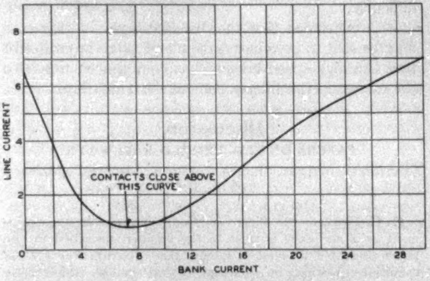

FIG. 3

FIG. 4

As is the case with all impedance devices, a directional relay is desirable. An induction disk, or integrating device, cannot be used for this application since its time of operation is entirely too long. The principle of operation of the device used for the directional feature depends on the fact that the current through the transformer bank at a station is very nearly in phase with the current flowing in the line. As a result, the relative directions of the instantaneous current values can be used for determining the direction of operation of a polarized relay. The transformer-bank current polarizes the relay as shown in Fig. 2, and the direction of operation of the relay then depends on the line current. The relay is very fast in operation under any fault condition that can cause operation of the impedance device.

The characteristic curve of one of these relays is shown in Fig. 3. The relay has been made to operate with current in the line alone so as to be independent of whether the transformer bank is connected in the circuit or not. Adjustments on the relay permit the relay to operate at any value of line current alone, which may prove to be desirable in a particular application.

Mention has been made of the fact that this impedance relay will operate for 90 to 95 per cent of the line length, and will not operate with faults just outside of the station at the opposite end of the line. However, in that case, the impedance relay at the fault end of the line will cause quick clearing of the breaker at that end, and thus leave only the breaker farther from the fault to feed into the fault. As soon as the breaker at the fault is open, the current through the breaker at the far end of the line increases to such an extent as to permit operation of a time-delay overcurrent relay. This relay operates after a time delay of approximately 1¼ cycles to cause clearing of this breaker. Thus, the sequence of operation for faults in the area where simultaneous operation is not obtainable, is that the breaker immediately adjacent to the fault opens instantly due to the impedance relay, and then the breaker at the far end of the line opens due to the operation of the time-delay relay.

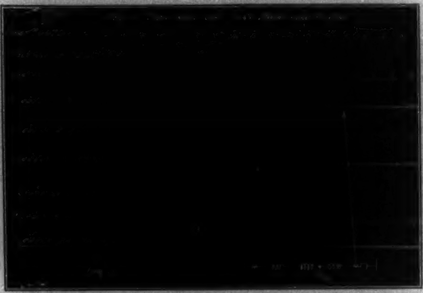

Fig. 5

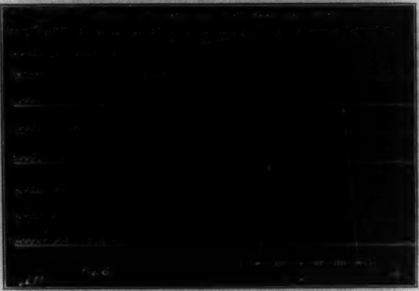

Fig. 6

In order to determine the efficacy of this system of relaying, a test setup was made. The diagram of connections is similar to that shown in Fig. 1 and the short circuit currents are as illustrated. Fig. 4 illustrates an oscillogram which was taken on this test system. The transformer currents and line currents are shown on the oscillograph record, the arrows from the diagram indicating each particular current. The voltages on the busses at each end of the circuit are also shown. Element No. 2 represents the current flowing through the trip coil of the breaker closer to the fault in this figure and Element No. 7 represents the current in the trip coil at the far end of the faulty line. As may be seen from the operation of Element No. 2, the trip coil of the breaker at the fault was energized immediately on the occurrence of the line trouble with the result that the heavy current was cleared in approximately ½ cycle. The trip coil of the breaker at the far end of the line, as shown in Element No. 7, was energized approximately 1¾ cycles after the fault occurred. This fault was taken in a position such that sequential operation of breakers was necessary. Figs. 5 and 6 represent faults at different points along the contact line. The oscillograph elements are the same as shown in Fig. 4. The total time of clearing for Figs. 5 and 6 was less than 1 cycle, and simultaneous operation of the breakers occurred. It is to be noted that the trip coils of the breakers at both ends of the line were operated almost simultaneously.

Thus, the use of a breaker with trip magnets permits the use of any type of relays desirable for any particular installation. This permits the use of pilot-wire schemes, line reactors, impedance relays, or any other relay system which seems best to fit a particular application. It permits system changes to be made which necessitate changes in the relay system at a comparatively small cost.

The scheme of high-speed relay protection described includes many of the standard protective schemes. The relays are modifications of those commonly used. The experience gained with this system would seem to indicate that any commonly used system of protection can be modified so as to be applicable for high-speed breaker operation.

**F. C. Hanker:** Mr. McNairy raises an interesting comparison as to the relative inductive influence produced by a-c. railway circuits and the usual power circuits. The only important difference between these two systems from an inductive-coordination aspect is the fundamental-frequency induction from the normal operating currents. The induced voltages from an a-c. railway system are due almost entirely to the earth return loop. In the case of faults to ground, the essential difference is only one of degree and not one of kind, assuming the power system to be grounded as is normally the case.

On the basis of equal fault currents on an a-c. railway system and on a 60-cycle power system, the induced voltages for the 60-cycle system would be approximately 10 times as great as for a fault on the 25-cycle system. This is due in part to the higher coupling factor at the higher frequency, and in part to the small earth current, which in the case of a four-track electrification is only approximately 25 per cent of the total return current, the rails carrying 75 per cent of the return. In the case of the electrification mentioned by Mr. Graves in his discussion of Mr. Wilcox's paper, the total fault current flowing from one station to a fault at an adjacent station is approximately 10,800 amperes. The 60-cycle current causing the same induced voltage would be $\frac{10{,}800}{2.4 \times 4} = 1125$ amperes, a value which is exceeded on many power systems for faults to ground. It is important to note that in the case of the railway system, the induction in sections not adjacent to the fault will be negligible. This is by no means true in the case of power transmission systems where the fault current will be of substantially the same value for parallels of several times the length of a normal railway distribution section.

Mr. McNairy makes the statement that the induced voltage from railway systems will be more frequent and of greater magnitude than the disturbances set up by an ordinary power circuit.

While it is undoubtedly true that such disturbances will occur with greater frequency on a railway system, we feel that the voltage for an equal exposure will be higher for the power system. Therefore, the only way in which we can reconcile Mr. McNairy's statements is on the basis of unequal exposures.

It seems to us that the outstanding factor in the coordination problem arising from a railway electrification is due not to the peculiar characteristics of the electrification system, but principally to the severe exposures which were created early in the development of the railway and communication services before the coordination problem was appreciated.

We note that Mr. McNairy states that a breaker and relay system designed for one-cycle operation will be the most desirable from an inductive-coordination standpoint. An effort to produce a faster breaker would probably cause undesirable transient induced voltages. This has been the basis of the design of all our high-speed a-c. circuit breakers, including the original New Haven breaker designed in 1922.

In Mr. Grave's discussion of Mr. Wilcox's paper it was brought out that on an actual system there were certain conditions of minimum generating capacity which required breaker operation on currents as low as 600 amperes or less, while under maximum conditions the breaker should not open on currents as high as 3900 amperes, this value being the sum of load current and current flowing to the fault in the good lines. That is, at the remote end of four parallel lines the faulted line may be carrying a current of 2700 amperes, the trolley with load may have a current of 3900 amperes, and the other two unfaulted trolleys may be carrying a current of 2700 amperes. Under minimum generating conditions, the faulted trolley current will be 600 amperes or less, the loaded trolley 1800 amperes, and the other two unfaulted trolleys 600 amperes. Under such conditions, will the protective system described by Mr. McNairy prevent the loaded and unfaulted lines clearing before the unloaded faulted lines? This situation would appear to be even worse if there are only two contact lines in service. It would appear that if the tripping point is set high enough to avoid clearing the loaded unfaulted lines, even sequential action could not be depended upon to clear the faulty line in such a case as Mr. Graves points out, since even after the breaker at the faulted end of the line has opened, the current at the other end may not exceed 1900 amperes. It may be possible to proportion the loading and saturating resistors to cover such a range. I should like to hear some quantitative data from Mr. McNairy on this point.

The trip-coil currents plotted by Mr. McNairy in Fig. 4 are based on a symmetrical short circuit. The duration of the first loop of current is frequently more than ½ cycle, and from his equations it would appear that if we assume $y = 45$ deg., the trip-coil current would pass through one of the flat spaces shown in the figure before having its first initial rise. This would mean that there would be no distortion in the holding magnet until the second current loop, which would mean more than ½ cycle delay before the breaker starts to open. Further, there is some doubt about Eq. 9 and a later one which make it difficult to predict what the effect of an unsymmetrical short circuit would be, and it would therefore be desirable to ask Mr. McNairy to explain further this phenomenon regarding an unsymmetrical fault.

**Sidney Withington:** It is of considerable interest that the apparatus described by Mr. Bardo, which represents the first examples of its type to be placed in commercial operation, should have proved so successful. The circuit breakers were built, as Mr. Bardo says, after some hesitation on the part of the manufacturers, who perhaps naturally were not enthusiastic in making development of this nature which the quantity then immediately in sight did not apparently justify placing upon a manufacturing basis. Subsequent demands are, however, an indication of the value of this type of equipment and the expense of this initial development has undoubtedly been warranted.

The operation of these circuit breakers has on the whole been very satisfactory, especially considering the fact that they represented a type of apparatus of rather radically novel design as compared with circuit breakers previously available. The difficulties which have been experienced were mostly of a minor nature and in practically all cases did not prevent proper clearing of the circuit. In most of the instances a minor revision in design has prevented a repetition so that in the future even better records may be confidently expected.

The installation has been of value in that by quickly clearing grounded circuits inductive effects on closely paralleling communication circuits have been prevented without consideration of booster transformers or other undesirable apparatus, and damage to the power distribution system on account of arcs at the point of fault has probably, in some instances at least, been eliminated.

It is entirely probable that on account of the obvious advantages in quickly clearing a circuit disturbance the use of high-speed circuit breakers may be expected to increase rapidly with the extension of heavy traction electrification.

**P. H. Hatch:** The problem of adequate circuit-breaker protection for electric locomotives and cars operating on the a-c. single-phase system is becoming more and more important as the magnitude of power supply is increasing. As Mr. Brown pointed out, sufficient space is usually unavailable on rolling stock to accommodate a circuit breaker capable of rupturing a dead short circuit. This has meant, on most electric railroads using a-c., that what circuit breakers have been supplied are used essentially as oil switches. Some method, therefore, must necessarily be developed for protecting locomotives or cars against the disastrous effects of short circuits occurring in the high-tension apparatus or wiring. On the New Haven, this has taken the form of a time-element relay so adjusted that the circuit breakers on the locomotives or cars, in case of short circuit, will not operate until sufficient time has elapsed for the sectionalizing breakers in the feeder and trolley circuits to trip.

It would seem that some arrangement for isolating a short circuit on a unit of rolling stock might be developed which would combine the advantages of lowering the pantograph automatically and at the same time introducing a definite time element between this operation and the appearance of the short circuit, which would give the sectionalizing breakers time to act. Hence, if for any reason the sectionalizing breakers have failed to act and the short circuit hangs on, the locomotive or car will be isolated. This, of course, involves the possibility of the power arc burning the overhead line in two, but where safety of personnel might be affected, this feature could easily be risked.

Referring again to Mr. Brown's paper, the development and application of high-speed circuit breakers for controlling the power supply introduces the problem of obtaining a relay sufficiently sensitive to operate when the current to the section affected is broken in less than a cycle's time. This has been very adequately dealt with in the paper referred to.

It takes little imagination to understand the many advantages of interrupting a short circuit before it has reached dangerous proportions. The general application of high-speed current-rupturing apparatus should go far toward simplifying the problem of protecting locomotives or cars. This will result in increased safety to operating personnel as well as substantial decrease of material damage.

**J. W. McNairy:** Mr. Wilcox's paper makes a statement that, with high-speed d-c. breakers, limitation of the magnitude of the short-circuit current is the only important factor in preventing flashover. I inferred from his statement that, in his opinion, the width or duration of the peak of the current curve, as shown by oscillogram, is of no importance. In this connection, I am particularly concerned with the synchronous converters when fed through a-c. lines of considerable reactance, where the short-circuit current is supplied largely from the kinetic energy of the machines. Limitation in the amount of kinetic energy taken out, (and the rate is high at excessive currents), is of considerable importance in preventing flashover because of the unbalance in armature reactions.

I should like to ask also if it is not practically impossible to stop the current rise on short circuit below the commutating value of a machine, making it, therefore, necessary to limit the time the current is above the commutating value to less than the length of time required for an arc to be carried by a commutator segment from one brush to another.

In the paper by Messrs. Monroe and Allen I wish to comment on the statement that the calibrating means, using reluctance in the magnetic circuit, is not as accurate as it should be. I should like to ask Mr. Monroe whether he feels that the inaccuracies are due to the use of the principle of magnetic reluctance, or are due to the method of utilizing the principle in present designs. I also inquire as to whether he has encountered sufficient inaccuracies from such a source to upset selective operation on this system.

Another comment I should like to make is on the statement that it is not possible to hold the high-speed breakers closed where it is desirable to burn off short circuits. A simple method can be provided with breakers of this type whereby an operator by means of an emergency button can increase the holding-coil strength to any desired value, and thereby obtain any tripping value desired for emergency conditions. Such a system may, of course, be operated by supervisory control.

One further statement I am interested in is that with reference to the high-voltage surges induced by high-speed operation, that is, that a voltage approaching twice normal may result across the circuit breakers in the d-c. circuits when operating. I believe this is a normal phenomenon with any type of circuit breaker.

When the short circuit occurs at the end of a feeder and is opened at the substation end, the inductive voltage of the feeder is opposite in polarity to the normal system voltage. While an oscillogram of the voltage across the contacts of the breaker will show double voltage, the voltage of the feeder in front of the substation changes from plus to minus, the actual voltage not being appreciably above the rating of the system.

A more important case is the operation of the circuit breaker on a locomotive where the voltages are additative. These need not be high-speed—any of the usual types of breakers may give voltages in the same order of magnitude as the high-speed breaker. This is particularly true since the high-speed breaker is effective in limiting the short-circuit current to a value much smaller than the short-circuit value, and it is, therefore, possible to break the circuit in less time because of this lower initial current.

**Caesar Antoniono:** In Mr. Wilcox's paper the statement is made, "Where feasible, a solid butt contact without auxiliary arcing tips becomes very desirable, etc."

That is a point about which I disagree with Mr. Wilcox. I don't think that a solid butt parallel contact as described in this paper is practical. When the breaker opens there will be arcing and burning at the top of the contacts. Any blisters that are caused by the arc will affect the alinement of the contact.

If there is any disturbance of alinement you have to cut the face down and in the field this takes a long time. For that reason I claim that the breaker is not practical from an operating point of view.

In Mr. Monroe's paper, which covers a different design of breaker, there is the statement, "Care of the high-speed circuit breaker contacts has been found to be almost unnecessary." That is a practical breaker from an operating point of view. In the same paragraph it says, "Due to the secure manner in which they are held together magnetically, instead of relying on a spring and latch arrangement." We find at times it is desirable to have the latch breaker rather than the magnetically held, for the reason that on interurban service, where interruptions of power are likely to occur very often, magnetically held breakers will open and then there is trouble in reclosing under low-voltage condition before the voltage is reestablished. Therefore, from experience I believe that there are conditions under which the mechanically latched breaker is preferable.

**D. C. West:** The term "high-speed" is relative, and assumes a finite meaning only when referred back to some standard of comparison. Since the real necessity for a d-c. high-speed breaker lies in the protection of 60-cycle synchronous converters, the speed required to protect such a machine, on dead short circuit across its d-c. terminals, is quite generally accepted as the criterion in d-c. practise. This has established the nature of present commercial designs, and the resulting breakers are capable of considerably higher speed than that which will provide quite adequate protection for other classes of conversion equipment, for motive equipment, or for d-c. distribution systems.

In order to understand the necessity for the very high speed required to protect a 60-cycle synchronous converter, consideration must be given to the inherent characteristics of the machine itself. It must also be borne in mind that although the 25-cycle converter possesses the same fundamental characteristics, the 60-cycle machine is considerably more susceptible to flashover because of its much more restricted design possibilities. The idea seems to be quite prevalent that a high-speed breaker protects a synchronous converter solely by virtue of the facts that it limits the ampere-seconds in the d-c. short circuit, considered from standpoint of heating under the brushes, and that it limits the peak value of current to be commutated. While these are undoubtedly important factors, the major effect is in the limitation of the angular displacement of the rotor from its no load phase position. Under normal conditions, the a-c. and d-c. components of current in the armature windings are opposed, and of such relative magnitudes that the resultant average armature reaction is approximately 15 per cent of that in a corresponding d-c. machine. The design constants of the machine affecting commutation are necessarily proportioned accordingly. On the sudden rise of d-c. incident to a short circuit, however, the machine acts temporarily as a d-c. generator, taking its energy from the inertia of the rotor. The a-c. builds up and supplies energy to the short circuit only as the rotor delivers its energy and drops back in phase position. This results in a temporary unbalance of the a-c. and d-c. components, with the latter greatly predominating and setting up a high armature reaction. Then when the d-c. is suddenly interrupted there is a large unbalance in the opposite direction, due to the fact that the a-c. continues to flow in proportion to the angular displacement of the rotor at the time the d-c. circuit is opened. The energy component of this follow-up a-c., which tends to restore the rotor to its no-load phase position, results in an excessive armature reaction since there is no opposing d-c. component in the armature windings. It is this armature reaction which, in most cases, is principally responsible for flashover of synchronous converters. In other words, such a machine will successfully commutate, for short periods, very large values of direct currents which, if too suddenly interrupted, will cause the machine to flash over.

The high-speed breaker must, then, limit the amount of energy taken from the rotor, and hence the angular displacement at the time of interruption, to such a value that the interruption of the d-c. circuit will not result in flashover. In speaking of d-c. high-speed breaker performance, the time to the point of current limitation, which with a given machine and circuit determines the peak value of current, is a better indication of its protective ability than is the time for total interruption. In fact, it would be preferable, having limited the current within a certain time, to reduce the current quickly to a value corresponding to the rotor phase displacement, and then reduce it very slowly to allow the rotor to recover at approximately the same rate and therefore maintain more nearly balanced relations in the armature. This is an impossible characteristic since the high magnetic blow-out effect which, as the author has explained, is necessary for high-speed limitation, also produces a high current decrement. It is possible to obtain the same effect, however, by applying the breaker to shunt a current-limiting resistor in series with the machine. Opening of the high-speed breaker then reduces the current to a value as determined by the resistor, usually two to three times machine rating, and the circuit is then interrupted by another breaker of ordinary speed.

Mr. Wilcox has pointed out the rather narrow design limitations which are imposed by the necessity for extremely high speed in the protection of 60-cycle synchronous converters. In order to provide protection under all operating conditions it is essential that the breaker be capable of this speed on *OCO* as well as on *CO* cycle. The design could be materially simplified by sacrificing a few thousandths of a second in speed on *OCO* operations, but the machine would not be protected in the case of the breaker being closed in against a short circuit. The breaker shown in Fig. 1 of the paper by Mr. Wilcox, was recently tested by the Commonwealth Edison Company at Chicago. The accompanying Figs. 7 and 8, show the oscillograph record of two of these tests in which a dead short circuit was applied to a 3000-kw., 600-volt, 60-cycle, 400-rev. per min. synchronous converter. Fig. 7 shows an *OCO* cycle and Fig. 8 shows a *CO* cycle. Within the accuracy of scaling values from the oscillogram, the speed and peak value of current are the same in both cases. The current was limited to 435 per cent of machine rating in 0.075 sec. and was completely interrupted in 0.014 sec.

**J. B. MacNeill:** Mr. McNairy discusses frankly the relative merits of oil and air circuit breakers as applied to contact-line service. I should like to add a few points to that discussion.

1. Regarding the effect of repeated operations on the two types it should be pointed out that it is the depreciation imposed by the short circuit on the breaker which determines its fitness for further service rather than any inherent quality of the design. The air breaker described by Mr. McNairy will open repeated short circuits. A properly designed oil breaker such as described by Mr. Wilcox will do the same. Each device, by reducing the duration of arcing to approximately one-half cycle, at the same time reduces the depreciation of the structure, whether this be oil depreciation, contact burning, or arc-chute charring. Without doubt, proper oil breakers will give service continuity and maintenance cost comparable to air breakers.

2. The space required by the air breaker seems to be considerable. Fig. 2B would indicate a length of approximately 12 ft. and a height of approximately 10 ft. 6 in., or a volume of approximately three times that of a comparable oil breaker.

3. It is questionable if insulation integrity even for 12,000-volt designs can be secured with an air breaker comparable to an oil breaker. The design shown in Fig. 7 of Mr. Wilcox's paper will stand 150,000 volts test. The same test on an air breaker would seem very difficult to secure.

4. I should like to ask Mr. McNairy if he considers the form of the current wave shown in Fig. 7 to be quite desirable. There seems to be considerable distortion on the last part of the half cycle. This is probably due to the enormous rate at which energy is expended in the arc. The statement is made that "energy is liberated in the chute at a maximum rate of 200,000 kw." when opening a short circuit of 30,000 amperes at 14,000 volts or 420,000 arc kv-a. This seems to be a very large rate for arc energy made necessary by the inherent limitations of an air breaker.

A device which would open the circuit after having pulled a low-resistance arc would, of course, reduce arc energy and incidentally would not distort the current wave form with consequently beneficial effects upon induced voltages.

5. Mr. Antoniono raised a question regarding the use of solid moving contact terminals of the high-speed d-c. breaker. Four years ago that was quite a new construction and naturally many of our older people questioned it the same as Mr. Antoniono has. It had to run the gauntlet of a great many tests, and after proving itself rather more satisfactory than average, it was accepted. It was new and would not have been accepted unless it was quite satisfactory. It has advantages in that it allows an exceedingly small moving contact to get high-speed operation.

**L. R. Ludwig:** Mr. Brown's paper brings to light an interesting trend in railway electrical engineering. Prior art has given us railway systems which, in addition to the major portions such as motors, require a good deal of auxiliary apparatus for protective and other purposes. Furthermore, protective apparatus has been required at many points within the system and on rolling stock itself. The concentration of this protective apparatus and the consequent elimination of part of it, in so far as this elimination is compatible with operating security, is a big step toward making electric operation economically comparable to that of steam, and so gaining the flexibility which electrical operation provides. It seems, therefore, that too much admiration cannot be shown for the combination of equipment which makes possible removing breakers, their mass and menace, from locomotives and cars.

One feature of the operation with pantograph-lowering relays which may be worthy of discussion, is the high-impedance transformer fault. That is, a fault to ground of a few turns of the transformer may not cause sufficient current to flow in the contact line to operate the substation breakers. The fault would probably grow more serious, and ultimately burn itself to ground at such a point in the transformer that the substation breakers would operate. This would entail additional destruction, however, and it seems that some measure of protection has been lost. It is almost obvious that the additional risk is cheaper than the eliminated breakers; nevertheless, it would be desirable to inquire if the last increment of protection cannot be gained without using the breakers. It is particularly necessary to protect the locomotives as completely as possible.

Two means of gaining this protection to high-impedance faults on the locomotives are self-evident. The first is the use of a small breaker on the locomotive, with proper relaying so that this breaker would operate only in case of a high-impedance fault. The second is a means of deliberately short circuiting the contact line if a high-impedance fault occurs in the transformer, and so forcing early operation of the substation breakers. Differential relay protection would give a full measure of protection to the transformer primaries, but only a partial protection of the secondaries could be secured. Further, the first method would require a breaker, and the second would possibly meet with some objection to short circuiting the contact line.

A striking means of gaining full protection presents itself as an academic possibility at least, if a protective system such as described in the paper "Superimposed High-Frequency Currents for Circuit Breaker Control" were used. It would mean actuating the substation breakers by connecting the contact line to ground through a condenser in case of a high-impedance fault, thus short circuiting the high-frequency system, but not the main power system. Also, full protection of both primary and secondary could be gained by using the differential of primary and secondary high-frequency voltage for relay operation.

**Chester Lichtenberg:** These papers give the impression that high-speed circuit breakers are new. They are not. They have been in service on electrified steam railroads for over 15 years.

There are two classes of high-speed circuit breaker. One has a mechanical latch for holding the contacts closed. The other has a magnetic device for holding the contacts closed. They should not be confused. A high-speed breaker will operate equally well when either means of holding its contacts closed is used. The type of contact-holding mechanism must be chosen for the particular application.

In some cases the high-speed circuit breaker has been condemned because when opened it may cause flashover of a d-c. machine. In such cases it is probable that the position of the breaker has been incorrectly chosen. It has probably been placed on the positive side of the machine. It has not been shunted with resistance. As a result, the current has been abruptly reduced from a high value to zero. So flashover has occurred.

Placing a shunt resistance across the high-speed breaker will not prevent the flashover of a machine if the combination is in the positive lead. If, however, the combination is inserted between the negative brush ring and the commutating or compound-pole windings, short circuit from flashover is prevented. The high-speed breaker on opening abruptly prevents the current's rising further. The arc drawn in the chute inserts resistance in the circuit. The current is quickly reduced to a relatively low value as set by the fixed resistor shunted across its contacts. Then another circuit breaker opens clearing the circuit. The resistance prevents an abrupt circuit clearing. It limits the resultant voltage rise to a relatively small value, too small to start arc-over. Being in the negative side the opening of the high-speed breaker would open any circuit through a flashover. For the flashover, if it occurs, takes place between positive brushes and ground *through the negative brushes!*

**J. T. Hamilton:** (communicated after adjournment) We operate multiple-unit cars having pantograph-lowering relays of the Westinghouse Electric & Manufacturing Company, 371-S2 and U.C.-8 types.

We have found that these relays protect the high-tension transformer windings but do not offer much protection for the low-tension windings of the main transformer, if this short circuits. In some cases where this short circuit has not been sufficient to operate the anchor-bridge circuit breakers, it results in the transformer being totally destroyed due to the overload being sustained.

Where one-car trains are operated, it may be necessary for the motorman or engineer to have access to the pantograph-lowering relay so that it can be reset. This is the practise followed on this property, our motormen being instructed that the relay in question can be reset if no damage is visible on the transformer of the car. We have found that the pantograph-lowering relay has operated sometimes without proper cause. As noted in Mr. Brown's paper, this may be due to the design of the relay in question.

On a-c.—d-c. equipment operating on a zone with d-c. overhead construction, it may be desirable to have a means of disconnecting the pantograph circuit from the main transformer, thereby preventing the d-c. from passing through the a-c. pantograph (if it should be raised accidentally) and then through the transformer with the resultant damage. This is easily taken care of by suitable a-c. circuit breakers.

**C. L. Doub:** (communicated after adjournment) From the standpoint of connection with the Illinois Central Railroad electrification in the layout of this distribution system and in the design, construction, and initial operation of the tie stations, I wish to amplify several points of the paper by Messrs. Monroe and Allen.

The large number of breaker openings during the early operating period has at times been referred to as "hair-trigger" action and cited as a fault of the high-speed breaker. It is significant that after this initial period the number of breaker openings reduced to a normal value (and in fact on some days there have been no breaker openings whatever), though changes have not been in the tripping circuits of the breakers. In the system there are 34 feeder sections which are fed by a total of 70 high-speed substation and tie-station breakers. It is therefore very well established that the so-called excessive number of openings was due to conditions other than the circuit breakers. Although making it difficult to locate the cause of the openings the breakers undoubtedly prevented a great deal of minor burning of car equipment and flashing of converters, and in all probability saved some cases of major damage. These excessive openings did not cause train delays, since breakers were immediately reclosed by substation operators or by supervisory control. On the other hand, they may have saved train delays, through preventing damage of equipment.

The several serious train delays charged to the breakers were due to defects in reset mechanism rather than in tripping, on account of which it was difficult to pick up a large legitimate load of rather steep wave front. The change in reset mechanism has entirely eliminated this fault.

Failure of selectivity occurred practically in no case excepting where two short parallel sections fed stub from a substation and were tied together by tie-station breakers. In this case selectivity is required between a tie-station and a substation breaker carrying the same current, with the same wave front, the only difference in the breakers being in excitation of holding coils from the line and from a battery, respectively. Even under such a severe requirement, selectivity is actually obtained except when the short circuit is remote from the tie station. In such a case the tie-station breaker holding coil receives too small a drop in voltage to make enough difference in speed of operation, since both breakers inherently have high speed. Other cases that have been considered possible failures of selectivity were in all probability due to bridging of section breaks by pantographs at the time of the transient, thereby actually imposing the fault on two or more feeder sections. The probability of this bridging is not at all remote in view of the large number of overlapping sections at interlocking plants and the considerable number of pantographs that are moving at one time.

Another outstanding feature is the great reliance on the high-speed breakers, which is unparalleled in any other similar heavy-duty apparatus. In spite of the large number of breaker openings no case was found where maintenance required more than light dressing of the contacts at periods of six months or more. At several times extensive tests were made involving 25 or more direct short circuits adjacent to circuit breakers within a short time and it was not even considered necessary to inspect contacts after such tests.

The simplicity of auxiliaries and circuits can well be emphasized. No relays or circuits external to the breaker are required for tripping. On this system the only relays are for reclosing and for supervisory control. Although the breaker itself is more intricate than the ordinary breaker, it is sufficiently strong and reliable to cause no difficulty in maintenance.

Practically all of the disadvantages of the breaker on this system have been eliminated or overcome. One disadvantage which cannot readily be eliminated is the difficulty of calibrating the breaker in the field, since currents of actual tripping value are necessary. Thus far there have been no differences in calibration demanding such field work, and perhaps the method supplied for correction for contact wear will prove sufficiently accurate for practical purposes.

On the whole, the disadvantages of the high-speed breaker in this installation have been so far overshadowed by the advantages that they need be given little weight.

**D. C. West:** (communicated after adjournment) In any sectionalized d-c. railway network such as that described by Messrs. Monroe and Allen, the feeder equipment must include two rather distinct operating features if a high standard of service is to be maintained. First, it must be selective between parallel feeder sections, so that only one section is isolated in case of fault. Second, it must provide positive discrimination between legitimate loads and faults. Since the latter of these two requirements has proved to be the more difficult, a brief statement of the problem, and of what has been accomplished in its solution, should be of interest.

The business of an electrified railway is to operate trains, and the electrical equipment is but a means to this end. It is essential that the feeder equipment protect the *service* as well as the distribution system, and it is with this in mind that the manufacturers have attacked the problem. Railway men are quite in agreement that the ideal feeder breaker would be one which would remain closed on any legitimate load to which it might be subjected under either normal or abnormal traffic conditions, and yet would trip out on any fault which might occur on the feeder section to which it is connected. The range of discrimination necessary to accomplish this will vary with the class of service and the type of distribution system, and for different traffic densities within a given system. In a very few cases the minimum short-circuit current will be of magnitude sufficiently greater than the maximum legitimate load peak to permit the use of an ordinary overload device. Usually, however, it will be found that the possible legitimate load considerably exceeds in magnitude the value of short-circuit current incident to a fault at the most remote point on the feeder section. In such cases discrimination is possible only through the use of some form of impulse tripping.

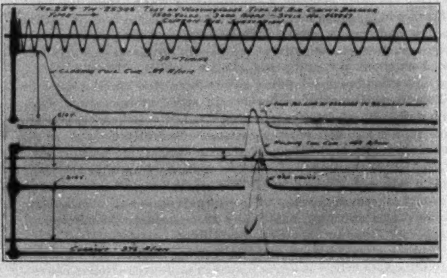

FIG. 7

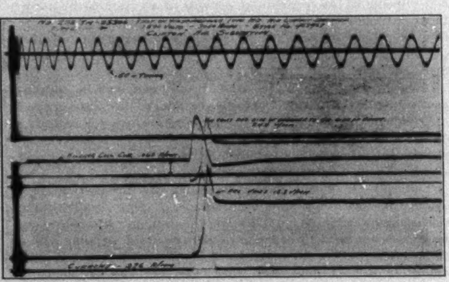

FIG. 8

It is fundamental that a legitimate overload on a railway feeder is the result of a traffic congestion. Railway men will readily appreciate the fact that it is at such times that it is most important to stick to the load up to the very limit of the current-carrying capacity of the feeder circuit. In other words, a legitimately overloaded railway feeder becomes a preference circuit which must remain closed, as long as the circuit is not at fault, in order to clear up the congestion. To open the breaker under such conditions, due to the magnitude of legitimate load, only makes matters worse and presents the possibility of serious delays to traffic. In considering the range of discrimination necessary, then, the maximum legitimate load will be that required to handle such traffic congestions as may occur on the particular feeder in question.

As has been brought out by the authors, the d-c. high-speed breaker, when equipped with an inductive shunt, has a combined overload and impulse tripping characteristic, and is therefore inherently capable of a certain degree of discrimination. Its possible inherent range of discrimination is determined within limits, by degree to which the overload feature can be minimized and the impulse feature can be magnified. The Commonwealth Edison Company, in collaboration with the Westinghouse Electric and Manufacturing Company, recently made a very comprehensive series of tests, at Chicago, on high-speed breakers for supplying power to the feeders of the Chicago Rapid Transit Company. It was demonstrated that the inherent range of discrimination was quite sufficient for the type and proportion of feeder sections comprising probably the major portion of the Rapid Transit system. The relatively high range on these breakers is made possible by raising the steady-current tripping characteristic to such a high value that it is well above the possible peak value of legitimate load swings, even under heavy traffic concentration. The breaker is therefore responsive principally to rate of rise and is affected to a relatively small degree by the magnitude of current flowing in the circuit. For example, with the breaker adjusted to a point well under the setting necessary to trip out on the 6500-ampere current increment due to a short circuit at the most remote point on one of the longer feeder sections, the steady-current tripping value is well above 15,000 amperes. The 8-car Rapid Transit trains require an accelerating current of about 2500 to 3000 amperes, and an oscillograph test on a 6-car train of the Chicago, North Shore and Milwaukee showed a maximum of 5250 amperes during acceleration. The actual discrimination obtained depends principally on the difference between the characteristic of the maximum single increment of load current, and that of the most remote short circuit. As is usually the case, the maximum load increment proved to be that due to the first point of control on the heaviest train. The 6-car North Shore train showed a single increment of 2670 amperes at about 8.4 millihenrys inductance. The inductance in the circuit of the 6500-ampere fault previously referred to, was about 3 millihenrys. It will be possible to handle a concentration of several trains on this section, and still isolate the most remote fault.

On most railway systems, and particularly in the case of steam-road electrification, even this relatively wide range will be found insufficient to provide positive discrimination throughout the system. By the use of properly designed relays energized from impulse transformers in the feeder circuits, it has been found possible to provide a range of discrimination sufficient to cover even the most difficult conditions encountered in service on the various types of systems. The most extreme example is probably that of the Staten Island Electrification of the B. & O. Railway, at New York, which was placed in service in 1925. Here, the high inductance of the heavy third rail made the problem particularly difficult. A feeder equipment was set to trip on a fault applied at the most remote point on the longest feeder section, and the oscillograph showed a current of 1950 amperes at the time the breaker opened. Then, with the same setting, an 8-car train, representing maximum future service, was accelerated immediately in front of the station. The breaker remained closed, although the oscillograph showed a single increment, on the first point of the train control, of 2350 amperes with a rate of rise of about four times that of the short circuit. The maximum accelerating current was 4350 amperes. Since the tripping is in no way responsive to the magnitude of current flowing in the circuit it can handle any number of such trains in a traffic congestion, up to the heating limit of the circuit, as determined by a thermostat on the outgoing feeder copper.

The system is double-track and completely sectionalized, including a tie station. Selectivity between parallel feeders is, of course, necessary and is readily accomplished by means of the same relays.

This case is cited as an illustration of what it is possible to accomplish by the use of devices designed solely for the purpose of obtaining the proper tripping characteristics. It would obviously be impossible to obtain this range of discrimination by using only the *inherent* characteristic of a device such as the high-speed breaker, in which the tripping is responsive only to the magnitude and rate of change of current. However, it is entirely possible to apply such relays to *any* type of breaker, and thus obtain the characteristic required for the particular conditions to be met. For example, it is entirely possible, through the use of relays, positively to isolate faults at all points on the feeder sections in the district between Brookdale and Harvey Substations, without the addition of any tie stations, and still permit the handling of larger trains and considerably heavier traffic.

**H. C. Graves:** (communicated after adjournment) Mr. McNairy has divided the time of operation of the high-speed circuit breakers into three parts as follows:

1. Time required for relay operation.
2. Time required for the separation of contacts.
3. Time required for extinguishing the arc.

He also mentions that by using breakers, as he has described, the time of relay operation can be eliminated.

To compare the speed of the breaker that uses relays, with those described by Mr. McNairy, it would be necessary that the time required for relay operation should also include the time necessary for the building up of the tripping current. Thus, if Item 1 should read: "The time required for relay operation and the building up of the tripping current," Items 2 and 3 could then be comparable on the different breakers.

Fig. 4 in his paper brings out the fact that the building up of the tripping current lags behind the building up of the line current. Assuming this wave in Fig. 4A to be a 25-cycle wave, the current rises to a maximum in 0.01 seconds, but the tripping current in Fig. 4B does not rise to a maximum until 0.016 seconds.

Also the tripping-coil current does not rise rapidly as does the line current, but rises gradually at first, and more rapidly later. This time lag is equivalent to something over ⅙ cycle, and relays suitable for this application are much faster than this. Oscillographs show that the trip-coil current builds up to a tripping value with practically no time delay after relay contacts close. Thus the building up of the trip current in the breaker as described by Mr. McNairy, is no faster, if as fast, as that described by Mr. Wilcox.

One important condition which must be met by the protective equipment on a system of this type can be described as follows: With a load adjacent to a station bus on a contact line, a secondary current of 5 amperes may flow away from the bus to the load. In Fig. 13, this current appears in the trip coil and the return path is not only through the saturating resistor but also through three other trip-coil circuits in parallel with the saturating resistor. The trip setting must be adjusted so as not to trip under these and other conditions such as the magnetizing of train transformer banks after the contact line has been disconnected, bus short circuits, etc.

After a train load has been connected until the fluctuations in the trip circuit have died out, a current increase of more than five amperes or more than ten amperes total fault current must flow to cause tripping. It is quite conceivable that this condition cannot always be met in practise.

Our objection to the scheme of connections as shown in Fig. 13 is that a change in the number of feeders connected changes the calibration of the other tripping circuits. The greater the percentage of change, the greater the effect.

If the breakers are so set that the above conditions will not cause faulty tripping of the breaker, then a comparatively large unbalance in line current must occur before the breaker will trip. If the breaker can be set so as to operate correctly under all conditions, it cannot be set so as to avoid a considerable amount of sequential operation. That is, the breaker at one end will open first and then the breaker at the opposite end will open. This is a bad condition from a standpoint of interference in signal and communication circuit, since the fault current is high and the distance of the exposure is possibly the entire distance between stations.

In Fig. 13 is shown the relay protection, including back-up relays, for a typical application. The back-up relay is shown as an impedance relay. This should prove to be a satisfactory form of protection in that it, alone, if of the induction type, should afford proper selectivity even if no other form of protection were included. However, here again simultaneous tripping of breakers at both ends of a faulty section would not take place and some time delay would be necessary.

**H. M. Trueblood:** (communicated after adjournment) I should like to add briefly to the discussion touching the relative inductive effects of single-phase railways and power circuits.

Aside from the other factors mentioned by Mr. McNairy, and by Mr. Hanker in his discussion of Mr. McNairy's paper, a comparison between the two systems should not, I think, overlook the greater probability, for short circuits on railway circuits, that faults will be of low or negligible resistance. Also, with multi-track roads, the inductive effects of current in the trolley-track loop may be of considerable importance in cases of closely exposed circuits, such as railway communication circuits carried on poles located on the right-of-way. Again, if a 60-cycle power line is provided with a ground wire or wires, such conductors carry a part of the return fault current, acting in this respect like the rails in the railroad case. Although they are not so effective in this function as the rails, they may carry substantial amounts of return current, especially if they are of high conductance. Mr. Hanker refers to the relatively small amount of induction in railway sections not adjacent to the fault. The significance of this, in a comparison of the two systems, depends upon the character of the exposure. While this factor is undoubtedly important so far as long, close parallels are concerned, it would be of minor weight from the standpoint of a type of exposure frequently met with, unless, in the railway case and not in the other, there is adaptation of substation location to the exposure conditions.

In Mr. Hanker's discussion, the statement that for equal fault currents the induced voltages for the 60-cycle system would be about ten times as great as for the 25-cycle railway system, is apparently based on 75 per cent rail current in the latter case. While this is a figure customarily used for four-track roads, it does not hold for a smaller number of tracks. With a single-track road, for example, the factor of ten mentioned by Mr. Hanker would be reduced to five or less. Either of these factors would, of course, be much larger than the ratio of actual induced voltages. In fact, as is suggested by Mr. Hanker's numerical example, fault currents on 25-cycle railways are ordinarily several times greater than on 60-cycle power systems, in cases where line impedance is an important factor, as it usually is where parallels are long enough to produce the higher values of induction.

A general comparison of the kind under discussion is difficult. To get numerical results, certain factors, such as line voltage, connected capacities, fault resistance, etc., must be fixed. For equal line-to-ground voltages, I believe it to be true that a three-phase 60-cycle system with dead-grounded neutral, when short-circuited to ground through zero impedance, would usually induce larger voltages than a single-phase 25-cycle railroad similarly short-circuited, provided exposure conditions are the same and such as to make the inductive effect of the current in the trolley-track loop negligible. This preponderance of the induction from the 60-cycle system tends to decrease with increasing length of exposure.

**J. W. McNairy:** The discussion by Mr. Graves, supplementing the paper by Mr. Wilcox, brings up many interesting points in connection with the selective operation of high-speed a-c. breakers applied to a network, particularly in connection with high-speed impedance relays.

The impedance of a given circuit may be easily determined from effective values of current and voltage under sustained conditions and used to actuate standard impedance relays. However, high-speed operation approaching that of other methods necessitates the determination of impedance by the current and voltage conditions existing for a small fraction of a cycle immediately following a short circuit under all possible transient conditions and presents a more difficult problem.

With low-power-factor circuits the ratio of instantaneous current to voltage varies for every point of the current wave. A relay utilizing the difference in torque between a potential restraining element and a current operating element receives a maximum operating torque on a low-power-factor short circuit near the zero point of the voltage wave where the current is a maximum. The restraining torque near zero of the voltage is necessarily relatively slight. At zero power factor there is, of course, no restraining voltage at the instant of maximum current.

It is entirely feasible to design over-current relays capable of closing contacts or mechanisms capable of unlatching in approximately 0.001 sec. after the trip point is reached. The design of an impedance device for such a speed of operation, however, is impractical because of the response to instantaneous current values and operation at the peak of the current wave where the voltage element has little or no effect.

It therefore appears essential that the speed of operation of an impedance device be limited so that the operating forces are dependent upon the effective values of both the current and voltage for at least a considerable portion of a cycle.

Further, where such a device is used, it should be noted that for a given applied voltage and a given external circuit both the instantaneous and effective values of the initial short-circuit current may vary over a considerable range. This variation results from the displacement of the short-circuit current wave and is dependent upon the instantaneous voltage at the time a short circuit occurs only and not on circuit conditions. With a completely displaced current wave the peak occurs one-half cycle after the incident of short circuit, at which time the voltage is approximately zero. The maximum current is twice that of a symmetrical current circuit, conditions being the same. High-speed impedance relays must, therefore, be set sufficiently high so that displaced exchange currents over unfaulted feeders will not operate these relays. The length of feeder which can be protected under short-circuit condition on a system of the type specified, with a symmetrical short-circuit current, is consequently limited. As a result, symmetrical short circuits at a considerable distance from a substation are likely to result in sequential operation of the two breakers at the ends of the faulty feeder.

It would appear, in view of the above, that a selective system based on the accurate determination of impedance from current and voltage conditions existing for a fraction of a cycle presents many new problems not associated with the usual type of impedance relay operating at slow speed.

In this connection, an accurate impedance device capable of operating in a half cycle must be equipped with a potential element which can respond to an instantaneous reduction in voltage, such as occurs at the instant of short circuit. The application of a short circuit in front of a station, at the instant the voltage is near the peak of the wave, requires that the current through the voltage restraining element of the relays at adjacent stations be reduced to a fraction of that existing prior to the short circuit in a very short period of time if true impedance is the basis of operation.

A further point is of interest in connection with the application of impedance relays to a system of the type which has been repeatedly discussed. The heavy current resulting from a short circuit at or near one substation greatly reduces the voltage of the high-tension line feeding adjacent substations. Impedance relays so designed that they will not operate with an exchange current of 2700 amperes over unfaulted feeders, with greatly reduced voltage, inherently require a relatively large current under load conditions where the restraining voltage is not appreciably reduced. This point is of very considerable importance in connection with any system where all substations are fed from the same source of power.

Sequential operation of circuit breaker at the two ends of faulty feeder, with short circuit near one station, is, of course, detrimental only when it results in a longer duration of the current over the feeder. When operating devices, such as impedance relays, receive an impulse only just sufficient to operate the resultant unbalanced torque between operating and restraining element which is relatively slight, full speed operation of the relay is difficult to obtain. Under such conditions the total duration of the short-circuit current over the feeder may not necessarily be shorter than that obtained by devices which do not initiate the operation until the second half cycle of the short-circuit current. This is particularly true where a considerable portion of a half cycle is required before release of the relay mechanism.

Referring to Mr. Hanker's discussion, there seems to be some misunderstanding as to the characteristics of a saturated current type of tripping circuit applied to the breakers described in the paper. The impulse voltage generated by the saturated current transformers is not a function of the total current through the corresponding breaker, but is a function of the current applied suddenly under short-circuit conditions.

If, therefore, the breaker supplying a faulty feeder is carrying a load of 1200 amperes and a short circuit occurs, resulting in an additional 2700 amperes in this feeder as well as three paralleling feeders, the initial current of 1200 amperes has practically no effect on the tripping circuit of a breaker connected to a faulty feeder. The voltage generated by this tripping circuit is proportional to the 2700 amperes increase resulting from the short circuit and is equal in the tripping circuits of all feeder breakers carrying the same increase. The only return path for the tripping current is through the saturating resistor common to all breakers, the resistance being sufficiently high to limit the current below the tripping point of the breakers.

By changing the value of the saturating resistor the ratio of the tripping point with a simultaneous current increase to the tripping point with a current increase through one feeder only can be made as great as desired. The trip point for a simultaneous current increase through all breakers can be made infinitely large by open-circuiting the saturating resistor.

It should be pointed out that the setting of the current-transformer trip is not determined by steady load requirements of the feeder. The limiting condition is the maximum increase in load which can take place instantaneously on the feeder. It is entirely feasible to have a breaker of this type set to trip with a current increase of 600 amperes, at the same time carrying a steady overload of any desired value without tripping. Due particularly to starting currents resulting when transformers of locomotives or cars are suddenly energized, it seems desirable that any protective system be capable of picking up such transformers regardless of the steady load conditions. The saturated transformer trip has the proper inherent characteristic. The effect of the pre-setting arrangement described by Mr. Graves results in a similar characteristic.

The selective operation of the differential circuit described in the paper is not dependent upon accurate setting of the breakers.

Fig. 4 of the paper was plotted to show conditions with a symmetrical short circuit because this is a limiting case in which the minimum tripping current results. The flat section of the tripping-current curve shown occurs only after the first tripping impulse has been supplied by the tripping transformers. In no case does a flat section precede the first tripping impulse. The calculations can be easily made to show the performance of the transformers with completely displaced wave by introducing a transient term in the equation for the line current. Numerous test records indicate that the tripping arrangement is, if anything, more effective when the current wave is displaced.

It should be pointed out that the exchange current betweent stations over the 11-kv. feeders results from the impedance drop in the 132,000-volt line between two substations and the step-down transformers supplying the short circuit directly. An exchange current of 2700 amperes results only with maximum generator and high-tension line capacity. A short circuit directly in front of one station reduces the voltage of the high-tension line to a relatively low value. If the drop through the low-reactance transformer and high-tension lines is sufficient to result in 2700 amperes exchange current per feeder between stations, or a total of 9800 amperes for four feeders, on the initial short circuit directly adjacent to one station, a very considerable increase in current will be realized as soon as the heavy short circuit is removed from the high-tension line, this current being effective in tripping the remaining breaker at high speed.

Mr. Hanker evidently interpreted my statement to the effect that the desired form of high-speed breaker is one which stops the current at the first zero after the first full half cycle to mean one-cycle operation. This is not the case, however, as a short circuit involving the time of a full half cycle rarely occurs under short-circuit conditions with the breaker described. A great percentage of test records taken on breakers of the type described in the original paper shows a single loop of current, a few show two loops, the duration of which in practically all cases is considerably less than one cycle.

Regarding the question of insulation of the air type breaker, I should like to know whether or not Mr. MacNeill feels that the 12,000-volt circuit is ordinarily subjected to voltages of the order of 100,000, or whether he feels the failures are due to local operating conditions, such as dirt, smoke, etc.

There are a great many pieces of apparatus connected to a 12,000-volt railway system which are not capable of standing 100,000 volts. There is nothing inherent in the design of the air breaker to limit the insulation for any reasonable requirement on 12-kv. systems. We feel that the type of insulation which is being used for the air breaker is particularly suited for the mechanical shocks of high-speed operation.

Another question raised was whether or not high voltages were likely to result from too rapid decrease of the current such as shown by Fig. 10. The particular figure referred to by Mr. MacNeill had plotted on it the voltage taken from the oscillogram. The voltage was 10,000 volts. Voltages have been checked by other recognized methods and I can say quite frankly that direct comparisons have shown less tendency to high voltage with the air breaker than with the oil types.

There has been no record published covering the liberation of energy in the oil breaker at rupturing currents near its interrupting ratings. It is my impression that with the heavy currents of 30,000 or 40,000 amperes there are a great many effects that come into operation of the circuit breakers, other than the magnetic blow-out effects, tending to cause high voltage. We know there are certain types of oil breaker which depend largely on explosion effects for opening the circuit.

I have an impression that any type of oil breaker, by virtue of those explosion effects, is quite likely to decrease the current more rapidly than a breaker where there is not available oil to furnish gas pressure for explosion. Some of this effect is present in an air breaker but we find from the experimental work we have carried on that the difference in this effect between the lighter and heavier currents is not nearly so pronounced as in the oil breaker.

Mr. A. C. Graves, Jr. has brought up some additional points in his discussion submitted after adjournment that require further consideration.

The statement was made that the tripping current as shown by Fig. 4A of the original paper does not reach maximum until 0.016 sec. after the beginning of the short circuit. It might be inferred that under any short-circuit conditions the breaker in question would not receive tripping current until the peak of this current is reached. Such a statement applies, however, only where the breaker is operating with current just sufficient to trip. Where a short circuit of any considerable magnitude is involved the trip point of the breaker is reached considerably in advance of the peak of the trip current and the breaker receives its tripping impulse in sufficient time to limit the current to a single loop in a majority of cases. The case taken for Fig. 4 is the limiting case where the current is just sufficient for operating the breaker.

As pointed out in an earlier discussion of Mr. Grave's description of impedance relay, it is difficult to see how an impedance relay can be constructed to operate on true impedance in a fraction of a half cycle, taking into account all possible transient conditions.

After all, an impedance relay receives its operating torque from the line current, this current usually reaching a maximum between one-quarter and a half cycle after the beginning of the short circuit. With the low power factor existing in short-circuit conditions, the voltage is a minimum, and, therefore, there is a pronounced tendency for the impedance relay to operate at this point of the short-circuit current wave unless a considerable time lag is introduced. While it is entirely possible to build relays which will close the tripping coil circuit in a very short time after the trip point is reached, such relays are usually not of the impedance type.

It is again pointed out that the setting of the saturated-transformer type of tripping circuit is not limited by steady load conditions. It is only necessary to set the circuit breakers so that the maximum load increase encountered in normal service will not operate when occurring on a single feeder. The limiting condition quite likely is that resulting from starting currents when energizing transformers, and any high-speed protective system which will operate in a fraction of a cycle must have sufficient leeway to prevent operation when transformers are energized at a time when the feeder is loaded near the maximum. The load pre-setting arrangement described by Mr. Graves in his original discussion of Mr. Wilcox's paper apparently permits a sudden application of load above the steady load being carried by the feeder in much the same manner as the saturated-current-transformer type.

One further point in connection with this application is that it has been repeatedly pointed out that under certain conditions on a given system the fault current over unfaulted lines between substations may reach 2700 amperes. This means that an impedance relay used for protection must be set so that 2700 amperes over the unfaulted feeder will not result in breaker operation, taking into account the fact that a short circuit at or near one substation reduces the voltage of the common high-tension system at adjacent substations to relatively small value. It is difficult to see how a relay can be made to trip at a load of 1200 amperes when the voltage is not appreciably reduced and still remain closed with an exchange current during short circuit of 2700 amperes between substations with the restraining voltage considerably reduced.

**W. P. Monroe:** Mr. McNairy asked two questions regarding our statement as to the inaccuracies of the calibrating mechanism.

We referred in our paper to the means of calibration which is obtained by a set screw which turns in and out of the holding-coil core and the marking of the calibration scale on a plate parallel to this screw. The scale is small but covers a considerable range. I believe it is obvious that with such a scheme of adjustment a high degree of accuracy would be difficult. He asked if this disadvantage has affected our operation. Since we have been in operation only two years and our initial adjustments are still largely in effect we believe our experience is not sufficient to enable us to know whether this will be a serious handicap. We anticipate that the wearing of the contacts of the breaker will affect the calibration somewhat.

In regard to holding in the circuit breaker on overloads, this can be done, as Mr. McNairy says, by remote control with a push-button, changing the calibration temporarily, but we were referring only to our own installation. In our unattended tie stations such a feature would entail undesirable additional supervisory control circuits.

In regard to high-voltage surges, without going into the theory of surges resulting from high-speed breaker operation on short circuits, I would say we mentioned this objection because it had been mentioned to us and we wanted to publish the fact that we had noticed no disadvantage of such effects, whether they exist in alarming proportions or not.

# Formula for Minimum Horizontal Spacing of Transmission Line Conductors as Affected by Danger of Contact in the Span

BY PERCY H. THOMAS[1]
Fellow, A. I. E. E.

THE present contribution is for the purpose of deriving a logical formula to be used as a guide in the determination of the minimum safe horizontal spacing of transmission line conductors, and is offered for discussion. By minimum safe horizontal spacing is meant the least spacing that will insure safety against short circuits between conductors due to their swinging together out in the span under the influence of wind or ice, and has no relation to the separation of conductors transversely at the towers, as required for securing the necessary clearance to the tower structure. The latter separation is usually controlling, but a number of cases occurs where the getting together in the span requires a wider spacing, such, for example, as long spans, or two circuit horizontal arrangements of conductors.

### THEORETICAL ANALYSIS

A study of these questions shows many erratic factors bearing on the danger of contact in the span between cables *horizontally* spaced, so that apparently experience data rather than mathematical calculation must be the final dominating consideration. However, these experience data are exceedingly scanty and difficult to interpret, so that a theoretical analysis is likely to be of real value.

### STEADY UNIFORM STATE

Considering a transverse wind, uniform in direction and steady in strength, we have a very simple case, for all the cables will be deflected in the same direction and by the same amounts, and will maintain exactly the same horizontal separation regardless of the direction and strength of the wind, even if the wind be straight up. Even if the wind blows at an angle with the direction of the line, the same condition exists. This is a very important conclusion.

An examination of the relations involved shows that with a strong cross-wind blowing the dropping of the ice on one cable leaving another cable in the same span coated would not have much effect on the relative side-swing of the two conductors in the case of aluminium cable steel reinforced, since the weight drops with the ice removed more or less in the same proportion as the wind surface is reduced. A special study should be made in each case for copper cable, where the balance is not so close. This action of steady state side-swing giving unequal displacements from ice unbalance is governed by entirely different conditions from the general case and is not hereinafter considered.

### NON-UNIFORM WIND CONDITION

When the wind is irregular in time or direction, or uneven at different points, there will be more or less tendency for the cable to depart from the true catenary curve and the possibility of contact occurs. Obviously, it is the transverse horizontal components of the deflection that tend to cause contact, not the vertical. With a strong wind blowing across the line, say 60 mi. an hour, air moves at a velocity of 88 ft. a second so that a time of perhaps 2/10 sec. elapses between the time when the air impulse acts on one cable and when it reaches the next cable in the same horizontal plane, so that there is no time for actual motion of one cable ahead of the other cable, due to the same high velocity wind impulse. Furthermore, it is exceedingly unlikely that with a *high velocity* transverse wind, there can be any great change of velocity or direction of the air in traversing the short distance between adjacent cables. In fact, the direction of the air must in general be substantially parallel to the ground, as there is no place for air to go elsewhere. This means that all cables in the first approximation are subject to the same transverse air impulses at any one instant of time, substantially. This is the reason, no doubt, that trouble with wires getting together in the span is so rare. Where the surface of the ground is curved or local obstructions exist close to the line, eddies will of course be produced. This is a vitally important case and will be considered later. The only exception would appear to be a cyclone on a small scale, with an axis inclined to the vertical by a large angle, this being practically beyond any experience of which the author is aware. But there are actual conditions in which cables have got together so that the necessary irregularities must sometime occur.

The most important active factor in preventing contact in the span with transverse winds is, no doubt, the restraining force of the tension in the cable which tends to prevent deformations of the catenary by the wind. In long-span construction, this tension is of very material amount and has a remarkable restraining effect. To deflect a vertically hanging wire carrying a 5000-lb. weight, one degree from the vertical will require a horizontal force of 85 lb. applied at the weight. A wind producing a pressure of 8 lb. per ft. must blow against 10.6 sq. ft. of area to produce such a force.

---

[1] Consulting Engineer, New York.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

Deflection of a cable from the catenary shape, however, will require much more force than the hanging weight, since both ends of the cable are fixed and it is already a convex curve. Therefore, in accordance with the law of increase of tension in a catenary with decrease of sag, which approaches the action of a toggle joint, the straightening out of other parts of the catenary cable, which must accompany bulges in the curve at any point, develop very high counter tension. A careful consideration of this matter will show that a catenary, under wind pressure and with small sag and high tension, is a very stable curve against deflection in the plane of the curve.

Furthermore, the swinging of cables will be largely "dead beat" on the wind (at least with transverse winds), and *will have no material pendulum or oscillatory movement.* It will be remembered that as a theoretic conclusion, pendulum action can occur only as the energy stored in momentum carries the moving body beyond a point of equilibrium against an elastic controlling force, thus paving the way for a return swing caused by the controlling force. The *velocity* of movement of the conductor in an actual span is relatively small, so that the kinetic energy stored in the moving cable cannot be sufficient to move it against gravity more than a few inches. No oscillatory movement of a few inches could be of serious importance in a transmission line. A velocity of one foot per sec. will cause a rise against gravity of only 0.02 ft. A velocity of 8 ft. per sec. would be required for the kinetic energy to be sufficient to raise the cable one foot against gravity. Thus it seems that due to wind across the line, there is little chance of conductors getting together horizontally.

Considering these principles in numerical relations, it may be assumed as an approximation that the danger of the deformation of the catenary and contact between cables is inversely proportional to the cable tension, other things being equal. It may be assumed also that it is directly proportional to the span, for obviously any given proportional deformation will give an actual displacement in feet proportional to the length of the span. Further, the displacing force will be proportional to the diameter of the cable representing the exposed surface.

The tension in any span taken as due to wind and weight will be proportional to the resultant of the wind and weights $w$, acting on the cable times the square of the span divided by the sag closely but not exactly.

The danger of contact would then be proportional so far as the above factors are concerned to

$$\text{Span} \cdot \frac{\text{Sag} \cdot \text{Diam.}}{w \cdot \text{Span}^2} = \text{Sag in per cent} \cdot \frac{\text{Diam.}}{w}$$

and might be written for preliminary purposes as

$$\text{horizontal spacing} = C \frac{\text{Diam.}}{w} \cdot \text{Sag in per cent where}$$

$C$ is a constant.

The effect of cable weight is to give greater tension and hence is favorable; but its effect is already included in the formula. The effect of diameter would seem to be relatively unimportant because both the force restraining (tension) and the force causing deformation (wind puffs) are affected more or less alike by diameter. This mathematical expression will be further considered below.

Longitudinal wind will cause a deformation of the catenary in a vertical plane but so long as it is a horizontal wind it will not tend to cause contact.

The vertical component of any wind, whether transverse or longitudinal, tends to support the weight of the cable and thus reduce the tension which, in turn, tends to render contact in the span more likely and this is probably the principal cause of such trouble. If the uplift is sufficient to take all the weight off the wire, there is tension due only to transverse components of the wind. Under such conditions, minor forces will be largely free to move the conductor about in an accidental manner, rendering contact much more likely. For example, a gusty longitudinal wind blowing under a line up a concave, rising hillside, would be very favorable for trouble, for the wind would have an upward component which would take off the weight and tension on the wires and the irregular transverse components would be free to bring them together.

A 6.5-lb. per sq. ft. upward wind component will take all the weight off a No. 4 copper cable and a 15-lb. wind all the weight off a No. 0000 copper cable.

For all aluminum cable, the respective corresponding pressures are 2.0-lb. wind and 6.2-lb. wind, and for aluminum cable steel reinforced 2.8-lb. and 6.4-lb. A 2-lb. wind on cylindrical surfaces corresponds to a velocity of 27 mi. per hour actual, and 6-lb. to about 60 mi.

Causes of steady upward components of wind would be configuration of the ground or natural and artificial obstructions, such as trees, buildings, sign boards, gullies, etc. In any particular case, from an examination of the ground, a sufficiently correct inference as to the directions of air currents can no doubt usually be made.

The breaking off of ice and heavy wind in an adjacent span or other causes may produce a pulling of a certain short length of cable from one span into the next, but this will effect danger of contact in the span only indirectly, and whatever conditions might be set up to render the line safe in general against transverse wind conditions in the span would probably protect also against the effect of pulling from one span to another.

Similarly, transverse conductor swinging may be carried from one span to the next, but such swinging is likely to be largely in synchronism for all conductors, unless in cases of very irregular ground configuration.

Apparently relatively short spans and very low stringing tension in the conductor tend to increase danger of contact, especially since it is highly probable that irregular wind and ground conditions do not exist over the whole length of any very long spans. This seems to be confirmed by reports of the behavior of extra long spans.

### SIDE HILL EFFECT

A consideration of side hill effects,—that is, lines located on side hills,—is very interesting. So far as the main wind pressure is concerned, it must follow the slope of the ground, and will have an upward or a downward component affecting gravity. Puffs, or eddies, may occur in other directions. This means a steady uplift conponent or a downward component on the cable, on side hills, decreasing or increasing the effect of weight. This may greatly affect the magnitude and direction of the resultant loading on the cable on steep hill sides.

With copper cable, under a transverse wind, the angle of cable deflection from the vertical with an uphill wind will be somewhat, but not greatly, increased. With aluminum cable, even when steel reinforced, the uplift will sometimes exceed the weight in stiff winds causing a swing above the horizontal. This does not appear, however, to increase the risk of contact between cables, except where erratic variations in the strength of the wind may cause large variations in the vertical plane. The variations in a vertical plane, however, would tend to restrain deformations in the horizontal plane on account of the fixed length of the cable. It is highly probable that except for a very few exposed hill sides there will be a tendency for the wind to have a less velocity on hill sides than in the open. On the other hand certain formations of the terrain have the power, like some tapering river estuaries subject to tides, to cause an increase of velocity by deflections and reflections.

The most important aspect of this uplift by a component of the wind on the cable, however, is the possibility of the uplift raising the cable at the tower up against the under part of crossarm. It is possible that this may account for some unexplained flashovers at towers. A glance at the tables showing dead weight and wind pressures will evidence the importance of this matter for aluminum cable, especially for smaller cables. A dead weight hung on the end of an insulator string may be very useful on certain exposed steep hill sides.

Considering the different effects of various metals, it may be said that plain aluminum is the most dangerous, not because of its light weight so much as on account of its lack of strength and the resultant loose stringing.

As between copper and A. C. S. R., the preference is not so clear—the greater density of copper would be of advantage at least in so far as it gives greater tension, while the greater strength of the A. C. S. R., if used to advantage, leads to a higher cable tension and makes a less percentage sag and gives decidedly the stiffer catenary.

A downhill wind on the side hill will increase the *apparent* weight of the cable, and in the case of A. C. S. R., may more than double it; but this will not greatly increase the resultant stress on the conductor.

### WIND PUFFS AND EDDIES

No definite measure of wind irregularities seems feasible. We know that air in wind motion will act like water at the bottom of the sea, for air is substantially incompressible for variations of atmospheric pressure. Where a current meets an obstruction, it will be deflected to the side, or upward, with an increased pressure, but without increase of velocity. If a current, however, is directed into a funnel shaped cavity or recess, there may be a somewhat increased velocity. Air seems to be subject to cyclonic effects more than water, but they do not seem to be especially destructive to transmission lines. Presumably, the danger from these puffs and eddies is measurable by the factors already discussed above.

The only way to take account of expected irregular variations in wind action in the proposed formula is to make a purely arbitrary alteration in the factor $C$ for any unusual conditions.

The only clear danger of contact in the span arises when, through deflection, by obstacles or a hollow formation of the surface of the ground, there is an upward turn of the wind, tending to raise the wire and thus give it slack within the span for accidental deflections.

Such obstacles and hollow surfaces must lie in direction along the line, so that a considerable length of span may be affected.

A typical example has been reported in a case where a transmission line paralleled the edge of a wood for a certain distance just outside. At this portion, the conductors were blown together in the span a number of times, presumably with the wind toward the wood. The obvious explanation would be the turning up of the wind strata blowing along the ground when they reached the wood, thus tending to raise up the conductors and allowing them to get together through the slack with no strong transverse pull to keep them all to one side.

The conclusion would seem to follow that each line should be gone over when installed for the purpose of locating wind obstructions or hollow shaped earth formation, and special precautions taken to prevent contact of wires wherever need appeared. It would be uneconomical to increase the width of structures over a whole line to meet a few determinable danger spots.

In the rare instances of contact in the span, known trouble has sometimes been due to other conditions than wind, which should be borne in mind. For example, electromagnetic forces due to short-circuit currents have been known to produce contact of wires, presumably caused by reaction due to the sudden cutting off of the short-circuit current, since heavy current of itself tends to separate the wires. However, except in a few extreme cases of heavy wires close together, there is little likelihood of this happening, although an examination of the forces should be made in all close cases. A transverse magnetic force per foot of about 17 per cent of the weight of the conductor would be required to deflect the center of the span 10-deg. from the vertical. This cause of contact is not further considered in this discussion.

Since the same spacing must ordinarily be used throughout the line, the constant $C$ should be determined by comparison with experience and should presumably be taken as applicable to the *normal tangent level span under Class "A"* loading conditions (or any other conditions that might be agreed upon) and it must contain factor of safety or margin enough to cover extra long spans and other variations. The apparent added risk from extra long spans is balanced partly by the much smaller chance of excessive air puffs and eddies on the large scale of the long span.

In choosing an actual formula, certain other considerations may be taken into account.

The jumping distance of the voltage is, of course, a factor to be taken directly.

The effect of the length of the insulator string appears to play little part in any of the above analysis and a long string would not seem to render contact more likely than a short string. Apparently antics in the middle of the span would not be greatly affected by the length of the insulator string. Nevertheless with our present imperfect knowledge of this subject, we would not be warranted in ignoring the length of insulator string. It may reasonably be assumed as an empirical formula that the horizontal spacing should include a part equal to the side deflection of the insulator string to the 30-deg. position. The normal spacing is certainly not likely to be reduced more than this due to the string. For pin type insulators this part becomes zero.

The above formula may then be set up as follows:

$$\text{Horizontal spacing} = C \cdot \text{Sag in per cent} \cdot \frac{\text{Diameter cable}}{\text{Class } A \text{ loading}} + D + \tfrac{1}{2} \cdot \text{Length of insulator string}$$

Where $C$ = A constant chosen arbitrarily for each line to take account of the sort of metal of conductors, wind conditions, character of terrain, etc.

$D$ = Jumping distance of line voltage—one foot for each 110 kv.

Sag in per cent is expressed without decimals, that is, 2 per cent is written "2."

If $C$ be taken as 4 for copper cable and 3.5 for A. C. S. R. and their sags in the normal span respectively as 3.75 per cent and 3.25 per cent the spacings for No. 0000 cable would be as follows:

For 44 kv. Pin Type Insulators

No. 0000 Cu. No. 0000 A. C. S. R.

$$4 \cdot \frac{0.5275 \times 3.75}{0.927} + 0.4 \,, \quad 3.5 \cdot \frac{0.564 \times 3.25}{0.764} + 0.4$$

$$= 9.0 \text{ ft.} \qquad = 8.8 \text{ ft.}$$

For 66-kv. Suspension Insulators

ditto $+ 0.6\, \tfrac{1}{2} \times 2.25 = 10.3$, ditto $+ 0.6 + \tfrac{1}{2} \times 2.25 = 10.1$

For 110-kv.

ditto $+ 1.0 + \tfrac{1}{2} \times 4 = 11.6$, ditto $+ 1.0 + \tfrac{1}{2} \times 4 = 11.4$

For 132-kv.

ditto $+ 1.2 + \tfrac{1}{2} \times 5 = 12.3$, ditto $+ 1.2 + \tfrac{1}{2} \times 5 = 12.1$

For 220-kv.

ditto $+ 2.0 + \tfrac{1}{2} \times 8.0 = 14.6$, ditto $+ 0.2 + \tfrac{1}{2} \times 8 = 14.4$

The above formula is the mathematical equivalent of the following:

In comparing two spans, *the horizontal spacing*, other conditions than those specified being equal,—

Should be twice as great in the first span when both have the same length, but the conductor in the first has one-half the tension of that in the second:

Should be twice as great in the first span when the first is twice as long and both have the same tension:

Should be the same in both when the first is twice as long and the second has half the tension:

Should be twice as great in the first when the diameter of the cable is twice as great,—the sag, span length, and loading per foot being the same in both:

Should be twice as great in the first when the loading is half,—the span length, the sag, and the diameter being the same.

In the formula tension and span length are the critical factors, one being as important as the other. The disadvantage of a long span can be made up by a higher tension and vice versa.

As instances of actual lines where an actual comparison can be made with this formula may be mentioned: (1) The Davis Bridge line of the New England Power Company with a two-circuit line of 12-ft. horizontal spacing on 110-kv. for No. 0000 copper wire; (2) A somewhat similar line of the Appalachian Power Company with 10-ft. spacing for 88 kv. for No. 0 copper conductor.

In conclusion it may be said that as a result of the various considerations already discussed, and of an examination of the proposed formula:

1. The safety against contact in the span depends apparently more upon tension in the cable and configuration of the ground than anything else.
2. The most dangerous conditions are probably those

in which the general wind velocity is not too high, this signifying low conductor tension, and is more or less parallel to the line, so that neither cable is blown far to either side, and in which there is an obstacle causing a local upward turn in the wind. The conditions will be worse in short spans and with small cables and large sags.

3. The cable conditions on side hills deserve much more consideration than they usually get.

4. The advantage of copper over A. C. S. R. or A. C. S. R. over copper, if either can be established, should be taken into account in the arbitrary constant *C*, as should also any variations of the terrain making the general conditions of any one line better or worse than normal.

The author has made considerable effort to locate examples of contact of horizontally spaced cables in actual service, where the conditions are known, for the purpose of selecting a constant for the formula derived above, but very few such cases have been discovered, although some 30 or more of the engineers in this country and Canada, with the best opportunity to know of such experiences, have been consulted. The following letters and extracts describe a few very interesting and pertinent cases and seem definitely to support the conclusions of the paper.

"THE MONTANA POWER COMPANY
Butte, Montana

August 2nd, 1927.

Mr. Percy H. Thomas,
120 Broadway,
New York, N. Y.
Dear Sir:

*Case 1.* We have a 60-mi., 100-kv. line built-on steel towers passing through the north end of the Tobaccoroot Mountains. The line is No. 0 hard drawn seven wire copper 10-ft., 6-in. horizontal spacing, 36-in. insulators strung at 1200 lb. tension at 32 deg. fahr., with 2⅜-in. Siemens Martin ground wires midway between phase wires and four feet above the phase wire plane. Ground wire was strung at 1500 lb. at 32 deg. fahr. This line had several spans ranging from 1000 to 1200 ft. crossing valleys and gulches more or less at right angles to the line, where the wind was apt to be severe and where it no doubt would strike one end of the span more than the other end and where it might have had a vertical component of at least 30 deg. to the horizontal. Many of these spans suffered short circuits during wind storms so that it was necessary to anchor the wires in midspan with hold-down anchors so run as to spread the two outside wires away from the middle wire at mid-span.

*Case 2.* We have a considerable length of 50-kv. pin type line consisting of three-phase wires and a ground wire all on the same crossarm at a uniform spacing of 42 inches. The phase conductors are each composed of three No. 8 wires, stranded, and the ground wire is the same size of steel. The wire was strung at 400 lb., 70 deg. fahr., and has developed several contacts on spans of 400 to 430 ft., crossing gullies in a rolling prairie country where the wind had an opportunity to cause eddies and other disturbances.

*Case 3.* We have personally observed a 1000-ft. span constructed similarly to Case 1 above and located at the top of a mountain ridge where a canyon led up to the top. Irregular blasts of wind coming over the canyon would cause the wires to deflect and in some cases this deflection would get sufficiently out of phase so that one wire would be practically in a vertical plane when the next wire was at nearly maximum horizontal deflection. We also observed that even under light wind, say, ten miles per hour, there were often irregular ripples running lengthwise over the wires. These ripples however, were not of great magnitude and could not have had anything to do with cause of contact between phases. The maximum ripple probably was not more than 18 in. Our observation leads to the conclusion that wires can be caused to swing out of synchronism to a considerable extent but we do not think it possible for two wires to swing in opposite directions at the same time under heavy wind conditions. Obviously, the greater danger of contact is in narrow valleys, or other broken topography, where the wind velocity is often excessive and also very turbulent.

As opposed to the cases of contact noted above, we have had spans 3200 ft. long at 22 ft. spacing strung at about 1200 lb. for ⅜-in. steel at 70 deg. fahr. over a straight smooth river channel, which were never in contact during 10 years of experience.

Yours very truly,
(Signed) A. C. Pratt."

NOTE: The 3200-ft. span described in the last paragraph would have apparently, a sag of approximately 15 per cent under the conditions of Class *A* loading. The formula would give for a copper conductor of the same size a horizontal spacing of over 40 ft. for a 110-kv. circuit, while no trouble was actually experienced with a 22-ft. spacing.

From another engineer there is a report that after experiencing trouble with all aluminum 3/0 and 4/0 cables on 500 ft. spans, with wires horizontally spaced 8 ft., with insulator string approximately 4 ft. long, this trouble being due to getting together of conductors in the span under the influence of wind, entire elimination of the trouble was obtained by the substitution of aluminum steel cable, 266,800 cir. mil, and 336,400 cir. mil, this being over a considerable length of line.

NOTE: If the sag with the aluminum steel cable be taken at 2 per cent, the formula would call for a 10-ft. spacing while no contacts have been experienced in many years with an actual 8-ft. spacing.

Extracts from report by Mr. V. M. McDonald, Supt., Transmission, Public Service Company of Colorado, received August 15th, 1927.

* * * * *

Span length, 400 ft.

Sag, 11½ ft.

Horizontal spacing, 10 ft. 6 in.

Voltage, 90,000.

Length of insulator string, 32 in.

Size and material of conductor, No. 1 hemp center copper strand.

Tension, 1150 lb.

Approximate wind velocity, (mi. per hr.), 85 at time of trouble.

Direction of wind with respect to conductor, right angles.

No sleet.

Location, side hill and nose slope.

When wires came together, circuit breaker tripped, conductor pitted.

This is the only known case where conductor came close enough to cause an arc. Wind was at right angles to line. Hillside deflected wind to an upcast underline that raised cables and they fell close enough to cause trouble.

We have several arcs between conductors on 44-kv., 4-ft. spacing triangle, due to burning weeds along railroad right-of-way.

NOTE: The last paragraph, while of value, does not relate to the swinging of conductors.

It is hoped that engineers interested in this matter will offer discussion on the above analysis, and will contribute any pertinent data they may have so that as much as possible may be assembled for the benefit of any who may have such horizontal constructions to install.

## Discussion

**M. G. Lloyd:** While Mr. Thomas has not attempted to give a complete analysis, he certainly has given us much food for thought on this problem. There is one thing I don't believe is made entirely clear. The tension in the conductor depends upon the loading condition. In the problems he has worked out, Mr. Thomas has taken the diameter of the wire bare, apparently, but has taken the loading with the ice on it. In other words, he has not taken the two constants that correspond one with the other. The tension in the wire, which is involved in deriving his formula, will depend, of course, on whether or not the wire is loaded.

From the discussion it seems to be clear that he considers the greatest danger of contact between the wires to be at the time of a wind with a vertical component acting upon the wire without ice upon it, and that seems a reasonable assumption as being the most dangerous condition. In working out the problems, however, he has taken the loading including ice on the wire, so that it doesn't seem to me his two conditions of diameter and of loading correspond to one another. I should think they both ought to be taken for the same condition.

Furthermore, in working out the examples on the fourth page, the author has assumed a definite percentage sag (percentage of span length). That percentage in practise, of course, varies with the span length and the values chosen would apply approximately for only a small range of span lengths. In the case of copper, for instance, where he takes the sag as 3.75 per cent of the span length, that would apply to a span length of, perhaps, 900 ft. or something in the neighborhood of that. For other span lengths that percentage would not be applicable and consequently, the results worked out would not seem to be applicable. He has not stated here what span length he is talking about. In working out these examples, if an entirely different span length is used, one gets results which are not at all comparable with practical values. For instance, if we take a very long span, the separations that are obtained by this formula, using that percentage of sag, come out in some cases entirely different from what would be considered practical values.

This formula, it is to be noted, brings in the first power of the sag as an element of the separation. I think experience has shown that more practical results are obtained by bringing in the square root of the sag rather than the first power. It is not clear just how that would be justified on theoretical grounds, as I do not see any imperfection in the author's reasoning to bring it in in the way that he does, but his formula will not be found very widely applicable when one considers a big variety of span lengths and the percentage sags corresponding to them.

In the statement on the fourth page, as to the application of the formula, the author says, "In comparing two spans, the horizontal spacing, other conditions than those specified being equal—," and he gives a list of a number of different conditions. As a matter of fact, you can't vary the things he mentions without varying the other quantities. It isn't a feasible, practical case to keep the other values constant when you vary those that he mentions.

For instance, in the first three cases, varying the tension, for instance, without varying the span length, the sag also will vary necessarily. You can't help but vary it or else vary the size of the conductor, which is another variable. That is true also if you keep the tension the same but vary the span lengths, which is the second case, or if you vary the tension and span length together, which is the third case. In the fourth and fifth cases, changing the diameter with the sag, span length, and loading the same, you will invariably change the tension. Of course, the tension doesn't appear explicitly in this formula, so that that does represent a case which is a practical one and the relations will be just as he has stated.

In the conclusions the author makes the statement, "The conditions will be worse in short spans and with small cables and large sags." I think in practise that doesn't work out because when you have the short spans you invariably have the small sags and probably high tension and you are consequently not likely to have trouble with short spans from this cause.

In the examples given in the letter quoted, the span lengths seem to run up to values that are not extremely high, but a thousand feet or so. I am sorry that in these examples of actual contacts that are cited there is nothing said about what the actual sag of these particular conductors was. If that could be given it would help to form some picture of the condition where these contacts have occurred.

On the fourth page where the values of actual separations of the Davis Bridge line and the Appalachian Power Company are compared to what is worked out in the formula, the sags do not appear to be given, so that it is difficult to determine how well they do fit the formula. It is possible that the percentage sag used in the examples worked out at the top of the page fit these particular cases that are mentioned but the data, unfortunately, are not given to check up on that point.

# Transmission Experience of the Public Service Company of Colorado

BY M. S. COOVER[1] and W. D. HARDAWAY[2]
Associate, A. I. E. E Associate, A. I. E. E.

***Synopsis.***—*The 100,000-volt transmission lines of the Public Service Company of Colorado, which were completed in 1909, extended from the Shoshone hydro plant on the Colorado River across the Continental Divide to Denver and represent pioneering in high-voltage transmission at high altitudes. This combination of factors, coupled with a rapid expansion of the whole system in recent years called for the satisfactory solution of many problems. The paper describes the system in a general way, and outlines some of the more salient operating difficulties that have arisen from time to time as well as their remedies. Brief mention is also made of the method of load dispatching.*

* * * * *

## INTRODUCTION

THE purpose of this paper is to submit the results of several years of operating experience of the high-voltage network of the Public Service Company of Colorado. Every transmission system has its own inherent mechanical and electrical features which are governed primarily by the amount of power to be transmitted, size of conductors, line voltage, spacing of conductors and towers, ratio of resistance and reactance and climatic conditions. Methods practised in load dispatching and the means of communication between various points on the system will vary for many reasons, depending largely upon local conditions and the best judgment of the engineers in charge. Furthermore, when any new problem in transmission engineering is encountered, or any change is contemplated, for the betterment of the service to be rendered it is always helpful to learn of the experiences of others who have been operating transmission systems.

A part of the transmission lines included in the present network operated by the company has been in continuous service for 20 years. Two years following this initial construction, the line was extended to a total length of 153.5 mi., from the Shoshone hydro plant on the Colorado River near Glenwood Springs across the Continental Divide to Denver, and from Denver to the Boulder hydro plant. Other sections of the network have been constructed during the past four years. With the exception of the transformers at the Shoshone hydro plant which were rebuilt last year, all of the original transformers and oil circuit breakers are still in service. This not only represents pioneering in the field of high-voltage transmission, but also progress in the art of design, construction, and operation. It is hoped that the data herein submitted will add to the information now available on such operating experience; also, that it may prove to be of some value to those having similar operating and maintenance problems.

## DESCRIPTION OF SYSTEM

The company serves the electric lighting and power requirements of practically all of the central, north central, and northeastern portions of Colorado. The area served covers approximately 750 sq. mi. and includes about 116,300 customers.

The high-voltage system comprises a total of 518 mi. of line at altitudes ranging from 5280 ft. to 13,700 ft. above sea level with 217 mi. of line operated at 100,000 volts and 301 mi. of line at 44,000 volts. The properties are segregated into what is known as the central system and the outside system, there being no means at present of interconnecting these two groups. Transmission in the central system is over 217 mi. of line at 100,000 volts and 181 mi. of 44,000 volts, and in the outside system transmission is all at 44,000 volts over 120 mi. of line. The map in Fig. 1 shows the territory served by both systems, as well as the location of the generating plants supplying these two principal transmission networks.

The generating plants connected to the central system, their capacity, and type of motive power are listed in Table I, while those of the outside system are listed in Table II. Since the outside system comprises only a small portion of the total properties operated by the company, the remaining material submitted in this paper will be confined entirely to the 100,000-volt transmission lines of the central system, a simplified diagram of which is given in Fig. 2.

The transformers supplying the 100,000-volt loop at Boulder Canyon and Valmont are star-connected, with the neutral solidly grounded. The step-down transformers at the Denver Terminal are delta-connected, on both high- and low-tension windings. The 100,000-volt transformers at Shoshone have been rewound recently for star operation on the high-voltage side, and the neutral has been solidly grounded. This connection has not yet been in service through a lightning season, and no data on the effect of this connection on flashovers are available. It has, however, greatly improved relay operation.

The 100,000-volt loop is equipped with impedance type protective relays, which have given correct sec-

tionalization for about 95 per cent of the flashovers. Until recently, flashovers on the Shoshone line have been cleared by manually lowering generator voltage. Automatic equipment was installed in October, 1927, for lowering generator voltage by inserting a large block of resistance in the generator field circuit.

The switching center of the central system is the Denver terminal substation, located two miles within the city limits of Denver. Three 100,000-volt lines converge there, and 60,000 kv-a. in transformer capacity is provided for supplying 13-kv. city feeders. The system operator and dispatching office are located at this substation. Private telegraph and telephone, and leased telephone lines are provided for communication with all parts of the central system.

## Altitude—Weather Conditions

The 100,000-volt line which crosses the Continental Divide presents a most difficult task of maintaining a high degree of continuous service. Reference to the profile of this line as shown in Fig. 3 discloses that the line originates at an altitude of approximately 6000 ft. at the Shoshone hydro plant; then traverses the Rocky Mountains, negotiating three passes—Hagerman at 12,000 ft., Freemont at 11,500 ft., and Argentine at 13,700 ft., thence to the Denver Terminal at 5280 ft. above sea level.

Shortly following the completion of this line, many interesting experiments were conducted and some of the results have appeared in Institute papers. The weather conditions during the winter season are very severe, making it difficult to secure all the operating data which often would be desired in cases of trouble. At the higher altitudes in the fall and spring there is an abundance of moist winds, whereas in the winter temperatures as low as 52 deg. below zero fahr. have been recorded. The maximum measured wind velocity so far reported is 165 mi. per hour. These conditions, combined with the heavy snows, make certain sections of the line almost inaccessible for a period of time, which means that the line must be thoroughly dependable from both the electrical and mechanical standpoint.

There are times when the winds are heavy-laden with moisture which freezes as it strikes the cold surfaces of the towers and conductors. This frost formation which usually builds out against the wind has been found to cover the conductors with an over-all dimension of 12 in., with still greater masses on the towers. Frost formations measuring 2 to 2½ ft. in thickness have been observed on the towers but so far there has been no failure of towers on account of this loading. Fig. 4 shows an interesting view of this ice formation; also the method of holding the jumpers in place against the high wind velocity. This particular tower stands at the top of Argentine Pass.

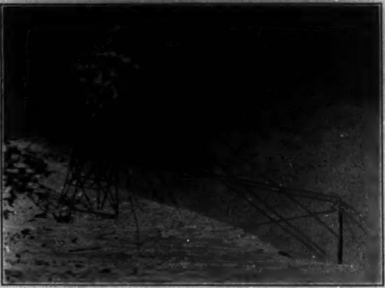

Fig. 4—Tower on Argentine Pass. Altitude 13,700 Ft.

One of the important factors taken into account in locating the tower line were snow and rock slides. Whenever it appeared unlikely to avoid these slides, heavy cribs were built around the towers to prevent their destruction. Fig. 5 shows the method adopted to protect the towers from such slides. The cribs are constructed V-shape and on the up-hill side of the tower, the intention being to split the slide. This type of protection, illustrated in Fig. 5, is constructed of heavy steel section securely anchored and filled with rock. During the nearly 20 years that the lines have been in operation, only ten tower failures have occurred attributable to slides. Of this number, one failure resulted in both the protecting crib and its tower being carried away by the slide. Landslides also have been the cause of several tower failures.

Considerable lightning is encountered on this line, covering an average period of 130 days per year. Many statements are made to the effect that insulation is the foundation of the electric power system; and true it is; yet any line exposed to storms, lightning, and slides, as previously mentioned, calls for a high degree of sturdiness in both electrical and mechanical design. The line across the Continental Divide has been in operation sufficiently long to enable a satisfactory solution to most of the mechanical problems in maintenance, but the problem of protection against lightning is still a very difficult one to master reasonably.

### Line Insulation

The original insulation was four Hewlett disk insulators on both dead-end and suspension strings with a 7½-in. spacing of disks on the dead-end and 6-in. spacing on the suspension strings. The ratio of dead-ends to suspensions was about one to fifteen. Two ¼-in. steel ground wires were put up for protection. Many difficulties were encountered during the first year of operation, principally on account of the lines being under-insulated and on account of mechanical failures of the ground wires. During the following year, the ground wires were removed, and a fifth disk was added to all dead-ends. This measure showed some improvement in service. During the following year, arc points were placed on both ends of all strings to provide a flashover path which did not destroy insulators. However, they do not reduce the number of outages caused by lightning.

In 1916, it was decided that the flashovers per annum were still too numerous, whereupon a fifth disk was added to all suspension strings and a sixth disk to all dead-ends. This reduced the number of flashovers approximately 75 per cent.

### NEW 100-KV. LINES

The Valmont-Denver line and the Valmont-Boulder line (see Fig. 2) were built during 1924, and placed in service during December of that year, which also marked the completion of the first unit of the new Valmont steam plant. These two lines tie in the plant with the Denver Terminal and with the Boulder Canyon hydro plant. American Bridge Company towers were purchased for both lines and designed for single circuit horizontal conductor spacing on the Valmont-Boulder tie, (see Fig. 6), while twin circuit vertical conductor spacing is used on the Valmont-Denver tie. Only one circuit was strung on the latter tie, and the second circuit will be added when the growth in load reaches such a point as to demand it.

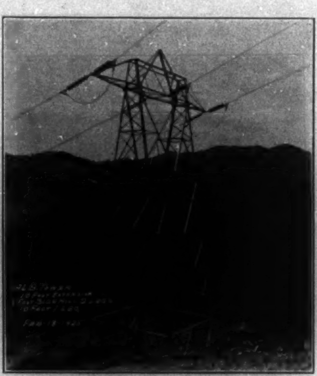

FIG. 6—TYPE OF TOWER USED ON VALMONT—BOULDER LINE

High mechanical strength, 336,000-cir. mil, A.C.S.R. conductors are used on both tie lines, the cable being made up of 30 strands of aluminum 0.1059 in. in diameter and 7 strands of steel 0.1059 in. in diameter. All suspension strings consist of seven No. 25622 O-B insulators spaced 4¾ in., and all dead-end strings consist of seven No. 26240 O-B insulators spaced 7 in. Arc points were initially placed on suspension clamps and at dead-end points on all strings, hoping to avoid breakage of upper disks by flashovers. Fig. 7 shows a typical failure of upper disk, and Fig. 8 shows type of upper arc points which are being installed.

### GROUND WIRES

Before going into a discussion of the interruptions to service on the 100,000-volt lines, it would be well to review the company's experience with ground wires. In the original design of the Shoshone-Denver and the Boulder-Denver lines, two ground wires were incorporated in an effort to avoid lightning troubles. These ground wires were soon abandoned and taken down on account of mechanical difficulties as previously mentioned. All towers on the new tie lines to the Valmont plant are so constructed that a ground wire may be added readily, but to date this has not been done.

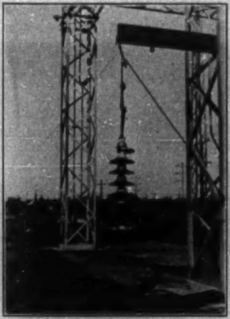

FIG. 7—UPPER DISK FAILURE WHEN NOT PROTECTED BY ARC POINTS

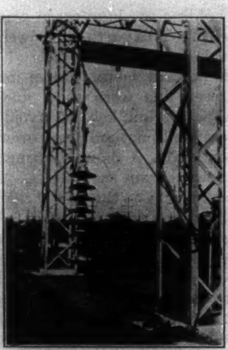

FIG. 8—TYPE OF UPPER ARC POINTS BEING INSTALLED

The lines from the Shoshone and Boulder hydro plants and the Valmont steam plant converge at a point about four miles west of Denver. From the Dry Creek substation, 2½ miles west of the terminal, the circuits from the Boulder and Valmont plants are carried on a double circuit tower line, the construction of which is illustrated in Fig. 16; while the Shoshone circuit is brought the same distance over a single circuit H-frame wood pole line, all on a common right-of-way. This double circuit of 2½ miles in length has been protected with a ground wire through two lightning seasons, with the result that there has been no insulator breakage on account of flashovers, and it is believed that there have been no flashovers during this period on this particular section.

### TYPES OF TOWERS

The Shoshone and Boulder Canyon lines were built on two types of towers, as indicated in Figs. 9 and 10. The tower shown in Fig. 10 was originally intended for double circuit use, with the second circuit directly below the upper circuit. This arrangement was found impracticable, and the lower arm was removed. Both of these towers were originally equipped for two ground wires, with clamps located at the connection of tower legs and the upper arm. Spacing was inadequate and ground wire failures were frequent, so they were taken down shortly after construction. Fig. 11 shows an extension recently added for carrying a ground wire over a portion of the Boulder line. The ground wire is flexibly supported in a standard conductor suspension clamp. The tower shown in Fig. 10, with a height of 50 ft. weighs 3600 lb. Fig. 9, 44 ft. high, weighs 1980 lb. In the Boulder Canyon–Valmont line built in 1924, the tower shown in Fig. 12 was used. It weighs 6000 lb., with a height on top of insulator string of 41 ft. The Valmont-Denver towers, Fig. 13, double circuit, built in the same year, weigh 7600 lb.

The tower shown in Fig. 9 appears to be very light and of flimsy construction, and guys are used on many towers. However, few tower failures have occurred. The somewhat flexible construction of these towers has probably relieved the stresses on them, and has permitted the guys to take some stress before tower members failed.

The steel poles, shown in Figs. 14 and 15, were used where right-of-way difficulties required narrow base construction.

### INTERRUPTIONS

Such information as has been recorded which may enable an analysis of the causes of interruptions is summarized in Table III. The data on outages have not been recorded with the degree of completeness which might be followed were a special study to be conducted on this phase of operation. The number of broken

conductors as given in the last column of Table III for each line during each year, are included in their proper places under other headings in the table. In some instances the failure was attributed to wind, while in other instances, the cause was not definitely apparent.

The prevalence of thunderstorms in the mountain regions causes many interruptions on account of lightning. The number of outages from this source amounted to 71.8 per cent in 1925; 77.8 per cent in 1926; and 62.9 per cent in 1927. The lightning report of the company for 1927 gives a total of 228 thunderstorms accompanied by a quantity of lightning, the first reported on March 30th, and the last reported on October 12th. During this period there were 56 trip-outs, and a total of 91 insulators had to be changed on account of disks being shattered.

One interesting relation which is evidenced by the summarized data on lightning as given in Table IV, is the comparison of the "miles of circuit per trip-out per lightning season" for the several 100-kv. lines. Bearing in mind the fact that these circuits are not protected by a ground wire except for the 2½ mi. of vertical-spacing double circuit from the Dry Creek substation into the Denver Terminal, the conclusion to be drawn is that flat construction without ground wire is least disturbed by thunderstorms. Following the observations which have been made to date on this particular phase of operation, the company decided that a ground wire properly installed is an essential adjunct to the system, and is proceeding with its construction, due attention being given to its material, location, method of attachment, and stringing tension.

TABLE IV
SUMMARIZED LIGHTNING REPORT

| Line | No. times lightning reported | No. times breakers opened | No. insulators damaged by lightning | Miles ckt. per trip-out per season |

The ground wire is flexibly suspended from "U" bolts or eyes in a standard conductor clamp and in a position where it is free to swing. In other words, instead of treating it merely as a doubtful appendix to the circuit, it is receiving the same careful consideration as though it were one of the main conductors.

In all but two cases where insulator damage occurred on the Valmont-Denver line as a result of lightning, the damage was confined to the string supporting the top conductor. This is in line with results to be expected on vertical type construction.

Table III indicates that substation troubles have somewhat frequently affected transmission line operation. Occasional 100-kv. bus flashovers occur in the indoor substations, although the busses are separated by twice the flashover distance between line insulator arc points. These troubles appear to be most frequent in the substations at Dillon and Leadville, which are approximately 9500 and 10,500 ft. above sea level respectively. Grounding the line neutral seems to have largely eliminated this trouble.

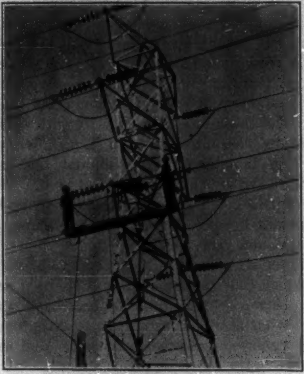

FIG. 16—TYPE OF DOUBLE-CIRCUIT TOWER

### INSULATOR FAILURES

When the new lines were built, seven close-spaced disks were used in suspension, with the expectation that cascading on flashovers would be avoided. Arc points were provided on the suspension clamp to avoid burning of the conductor. Operating experience indicates that practically all flashovers damage one or more insulator disks at the top of strings. A theory has been proposed by the insulator manufacturers that the swinging bracket used for mechanical reasons in supporting suspension strings causes a detrimental distribution of electrostatic flux. Upper arc points are being installed at all points to protect the insulators from flashover arcs.

It is of interest to note that in the 50 flashovers which have occurred on the new lines, in all but one case it has been possible to restore service immediately without repair or insulator replacements. In the one case excepted, insulator hardware was burned through on account of a relay failure, and the conductor was dropped. This string is shown in Fig. 17.

### CONDUCTOR FAILURES

The failure of power conductors and ground wires as a result of vibration is a subject which has received considerable attention in recent years. Efforts have been made to determine those factors which contribute to destructive vibration and valuable data have been assembled. Within its lifetime of operation the Public Service Company of Colorado has experienced approximately 200 conductor failures attributed to various causes. The majority of these cases of trouble occurred in the early years of operation and repetition was prevented by the use of a flexible joint between the conductor and the insulator for suspension type construction and at the towers for dead-ends.

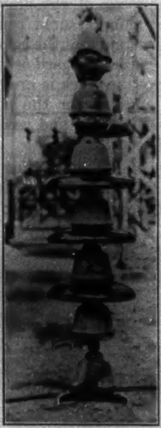

FIG. 17—INSULATOR HARDWARE BURNED THROUGH

One interesting and peculiar type of conductor break began to develop in 1921 for the first time and has been showing up since at an increasing rate. Horizontal spacing is used on the Shoshone-Denver and on the Boulder-Denver lines, these lines having been constructed in 1909. All conductors as initially installed consisted of six copper strands with hemp center. Referring to the profile in Fig. 3, No. 1/0 conductor was strung from Shoshone to Leadville; No. 1 conductor from Leadville to Dillon; No. 1/0 conductor from Dillon to Denver, and No. 1 conductor from Boulder hydro plant to Denver with a tension of 1250 lb. at 60 deg. fahr. Steel towers are used the full length of these lines, with a normal span length of 700 ft., a minimum of 300 ft., and a maximum of 2700 ft. The general direction of the wind is parallel to the Shoshone-Denver line and at right angles to the Boulder-Denver line.

The probable phenomenon surrounding the type of failure which began to show up on the Boulder-Denver line in 1921, and not until in the spring of 1927 on the Shoshone-Denver line, has aroused much concern for the reason that it has been necessary to replace 11.4 line mi. of conductor to date on the Boulder-Denver line on account of failure of individual strands. A close examination of the breaks in the individual strands reveals that some strands fail from crystallization, some from elongation, and some from an apparent crystallization. If the length of the conductor between two points is divided roughly into thirds, these breaks occur most frequently in the third of the span length next each point of support, and very rarely in the middle third. The breaks in a single strand are found to occur from ½ in. to 4 in. apart, while these breaks appear to be in a stage of development along the conductor grouped at intervals of 6 in. to 6 ft. apart.

FIG. 18 FIG. 19 FIG. 20

STRAND FAILURES

All but one of these conductor failures have occurred on the Boulder-Denver line and in that section of the line which traverses what is known as the Rocky Flats, just north of the city of Golden, where the prevailing severe winds are at right angles to the transmission line. From observation, it is found that in addition to the swinging of an entire span length of one conductor, there are segmental vibrations set up. These segmental vibrations promote crystallization, which in time develops a slight fissure in the strand next to the hemp center. Then there is a possible electrolytic action set up following the creation of the fissure, the metal being conducted through a film of moisture and deposited on the hemp center. This line of reasoning does not always appear to be borne out by facts; for while there is a noticeable deposit of copper on the hemp center in some instances, there are other instances in which the hemp is very badly disintegrated with no sign of copper deposit and still others where the hemp is in a high state of preservation with no sign of copper deposit. Another thought which has been advanced is that the wire as received from the mills contains slight flaws which progressed under vibrational stress. Neither theory seems to provide a satisfactory answer.

The appearance of a strand failure enlarged to approximately 20 diameters may be seen in Figs. 18, 19, and 20. These particular ones are three of a total of four strands in a conductor break having the same characteristic appearance, while the other two strands of the conductor failed as a result of elongation with a slight amount of burning as the conductor finally parted. All six strands parted within a distance of 11 in. along the conductor. It will be noted that a very definite crater exists, partly as a result of the disappearance of metal, and partly on account of the necking down of the small amount of metal left around the periphery of the strand. These three illustrations are typical of all those investigated where the fissure had progressed nearly all the way across the strand.

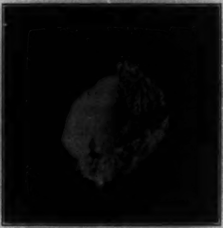

FIG. 21—STRAND FLAW DISCOVERED AFTER CONDUCTOR WAS REMOVED FROM LINE

Fig. 21 shows an enlargement of a break completed by hand. As the strand was unwound from the conductor it parted with less effort than the breaking of a thin toothpick. In other words, it virtually fell apart, so high was the degree of disintegration. The break was a little more uneven than in the three preceding illustrations, and could not be focused uniformly. It may be seen, however, that the fissure had progressed more than a quarter of the way across the strand with the same characteristic stream lines converging at a point of discharge as in the other strands, and that the process of creating the defect is in two stages; one progressing V-shape and the other in the shape of a fan.

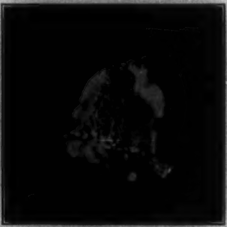

FIG. 22—STRAND FAILURE PRODUCED MECHANICALLY

Fig. 22 is an enlargement of a strand break produced mechanically and submitted only to compare its fracture with those produced in line service. It may be mentioned that the reason the enlargements do not appear to be more circular is on account of the fact that the specimens had to be tilted slightly under the lens in order to use reflected light. A fact of some note is that, to date, the phenomenon described above has only occurred on the No. 1 size conductor, there being none to date on the No. 1/0 conductor.

Another reason which may be advanced for these failures is that the process of wire drawing in use at the time the cable was manufactured resulted in the wire being drawn too hard, and that the conductor vibrations set up by the wind causes any hard or brittle spots in the wire to crack. Once the crack is produced, it is only a question of time until under the possible combined influence of corona discharge and repeated flexure, the ultimate break will occur.

The abrupt rise of the mountains from the plains produce a change in temperature sufficient to keep air currents crossing the Boulder-Denver line almost continuously. It has been observed that even slight air currents will set up and maintain vibrations which appear to have a greater amplitude at times than the segmental vibration caused by high winds. It is regretted that no specific data have been obtained on these lines which might enable some possible relation to be established among temperatures, length of span, stringing tension, frequency and amplitude of vibration.

FIG. 23—PACK TRAIN USED ON CONSTRUCTION AND MAINTENANCE

To date no vibration troubles have been experienced on the aluminum conductors.

## MAINTENANCE AND OPERATION

Maintenance methods have been developed which enable the patrol men to make repairs with the minimum of assistance. This has been made necessary by the inaccessibility of many parts of the line. Fig. 16 illustrates the working platform and "slack puller." The platform is suspended from the arms and guyed to the base of the tower. It provides a stable platform at a convenient height for work on dead-ends, and is safe even in high winds. When necessary, hook ladders and planks temporarily attached to the towers are used for work on suspension strings.

The "slack puller" is a crank-operated tension device with sufficient gear reduction to enable one man to exert a tension of 10,000 pounds. Its use dispenses with heavy blocks and luff lines in insulation replacement work. This device was invented and patented by the Transmission Superintendent of this system.

In the mountainous regions where the line can be reached only over steep, rocky trails, burros are used in pack trains for transporting material. Fig. 23 shows this means of transportation.

### SAFETY IN OPERATION

There has been no fatal accident to any employee on the 100-kv. lines during the entire period of operation. One man was seriously injured in a fall from a temporary platform because he was not using his safety belt. There have been two accidents fatal to men not employed by the company. One occurred when a young soldier climbed a tower on a dare and fanned the conductor with his hat. The second accident killed a sheep herder and his horse when he rode into a line having insufficient clearance.

Grounded guard wires have been installed under the lines at important highway crossings, and the towers have been fenced or otherwise guarded in places which are particularly accessible.

Responsibility for safe operation of the lines rests largely with the dispatchers. Patrolmen keep the dispatcher informed of their movements, and when patrolmen do not report on schedule, additional help is sent out. This protection is particularly necessary in mountainous country where blizzards are not infrequent, and where falls or snow slides may disable men.

Safety and first-aid work is emphasized, and a wholehearted attempt is made to "sell" the idea of doing work safely, rather than to enforce rigid rules of safe conduct. Monthly meetings are held where safety and operation are discussed, and where any employee may voice pertinent ideas or opinions.

Linemen are divided into groups and if no time is lost on account of accidents to any member of the group in a three months' period, each member is given a pair of pliers, suit of overalls, pair of gloves, or similar useful article.

### CONCLUSIONS

No exceptional difficulties have been encountered in high-altitude operation; jumpers at dead-end towers should be supported where wind velocities are high.

Insulation problems are no more serious than at sea level.

Arc points appear to be desirable at both ends of insulator strings. Copper and steel conductors operating above the critical voltage for corona for many years do not show unusual depreciation.

Horizontal configuration appears to be more desirable than vertical configuration, and properly built ground wires are probably effective.

Satisfactory relaying of high-voltage lines has been accomplished without great difficulty.

## Discussion

**Harold Michener:** Some of the conductor failures were said to be due to wind, or thought to be due to wind. I should like to ask if it was thought that the wind forces caused those conductors to part without burning or whether it was the wind that blew the conductors into the tower or the two conductors together, after which they burned down.

**M. T. Crawford:** The Puget Sound Power & Light Company has operated a 120-mi., 110-kv. line across the Cascade range for about six years. Although the altitudes are not as great as those described in this paper, the ice and snow formation and weather conditions appear equal if not worse. The experiences on this line were described in a paper presented at the Pacific Coast Convention of the Institute in October, 1923.[1] Subsequent to the presentation of this paper, additional reconstruction work was done, following which there have been five years of very successful operation without a *single* interruption due to failure in the extreme loading section.

As finally reconstructed this line is built on standard steel towers with horizontal conductor arrangement, using 350,000 cir. mil 19-strand hard-drawn copper cable. No dead-ends are employed, all wires being held by suspension strings, each consisting of two standard strings yoked together in parallel, and free to swing at both tower and clamp. This method of construction permits free movement of conductors lengthwise of the line and eliminated the troubles which were first experienced from wires being jerked in two at dead-ends by the falling off of large sections of the snow and ice formation which builds up to 2 ft. in diameter.

All of the diagonal and horizontal angles were removed from the steel towers up to the snow line and in their place heavy angles were installed paralleling the corner leg members, eliminating the serious trouble which was at first encountered by the bending and shearing of angle braces by the settling of the heavy snow crust in the Spring.

Fortunately lightning is infrequent in the Puget Sound region. Only six interruptions have occurred in the five years from troubles of all kinds on this line, two of which were from lightning.

I should like to ask the authors of this paper if the troubles from broken conductors on the Shoshone-Denver line, noted in Table III, included any breakage of the character referred to above, due to the ice loading or to jerking action at times of dropping off of such loading.

**H. H. Plumb:** I should like to ask the authors if they have evidence of any unusual wind velocity at the high points across the passes. In my experience the evidence has been very plain that the wind velocity at the top of a fairly high mountain has been exceptionally high, of the order of a hundred miles per hour. That figure has been obtained by taking the size of the ice coating at the time when failures occurred, which was about 4 in. in diameter on a ⅜-in. diameter conductor of steel, and calculating the wind velocity that must have been present to break such conductors.

I should like to ask the authors if they have encountered any such high wind velocities as that.

**G. B. McCabe:** I wish to question the wisdom of leaving that word "probably" in the conclusions under the next to the last paragraph—"properly built ground wires are probably effective."

---

[1] *Transmission Line Construction in Crossing Mountain Ranges*, M. T. Crawford, TRANS. A. I. E. E., Vol. XLII, 1923, p. 970.

In the case of the Detroit Edison Company, we should leave the word "probably" out of such a statement.

We have a section of a double-circuit, 120,000-volt line between Trenton Channel and Marysville power houses, which runs through a particularly bad area in respect to lightning. During the 1925 lightning season on this double-circuit line in this particular section between Marysville and Superior Substations we had 44 lightning storms and 107 trip-outs. The following Winter we equipped the bad section with ground wire, a single ground wire of the same size as the conductors, *viz.*, No. 000 supported in the peak of the tower, and during the next or 1926 lightning season, with 34 electrical storms we had only seven trip-outs. We therefore feel that the use of ground wires is decidedly effective.

**W. D. Hardaway:** Mr. Michener asked if wind forces caused the actual failures. My impression is that they did not. I think that at the time the worst trouble was being experienced the line was equipped with ground wire at that point and the conductor was blown into the ground wire and burned, or at least nicked, and failed later.

Mr. Crawford's discussion was certainly an "eye-opener" to the operators in Colorado. Our snow loading and ice loading isn't as severe as that. We have large volume of frost formation but it isn't very heavy. Also, his service record of six outages in five years was certainly very interesting to us.

As to failures by jerking action of ice loading, I don't believe that has been experienced for the reason that the ice loading is not very dense. It is sometimes a foot in diameter but not heavy. Some of the failures which have occurred have been where the line was buried under snow and the snow suddenly settled and took the line out. It is rather interesting that some of those lines have operated actually under the snow, through tunnels in the snow.

Mr. Lloyd spoke of whipping of conductors on the Argentine Pass. The particular experience given in Mr. Thomas' paper was obtained on another line, Boulder Canyon, on a very steep hillside, and with a lighter conductor than the line across Argentine. However, there has been some wind trouble at Argentine which was helped by dropping the middle conductor and obtaining increased separation vertically.

The wind velocities which were mentioned are of interest to us. I can't speak with definite knowledge, but we have reports of 150-mi. wind velocities on Argentine Pass. Of course, those velocities should be corrected to sea level. They do not have as destructive action at 13,000-ft. altitude as they would have at sea level.

# A-C. Elevator Motors of the Squirrel-Cage Type

BY E. E. DREESE[1]
Member, A. I. E. E.

***Synopsis.**—This paper sets forth the features of squirrel-sage motor design which differentiate it from standard motors. Much of the paper is devoted to the two-speed motor with two separate stator windings having speed ratios of 2/1, 3/1, 4/1, and 6/1. The two-speed motor with a single winding is limited to the 2/1 ratio. Higher ratios are necessary for high elevator speed and low and accurate landing speed.*

*The elevator motor is subjected to continual starting and stopping. The effects of inertia in such service are considered in connection with motor heating.*

*The proper division of slot area between the two stator windings and the problem of building a rotor with proper characteristics on both speeds are explained.*

*Noise elimination is necessary in elevator motors. The effect of this requirement in design is considered.*

*The effect of rotor skew is compared to the effect of distributed winding in the stator. The quantitative effect of skew is embodied in a constant called "skew factor."*

*The possibility of transformer effects between the windings of a two-speed motor is explained and methods of correcting to eliminate circulating currents are indicated.*

* * * * *

---

THE induction motor as developed for elevator drive is a highly specialized type of machine. Slip-ring motors have been used, but the complications of control and the difficulty in eliminating noise have caused them to give way to the high-resistance squirrel-cage type. The high-resistance rotor gives a speed-torque characteristic which insures that the motor will have no points of mechanical instability and the motor will not pull-out and stall. The high-resistance rotor can be designed to give the maximum torque when starting and the torque per ampere is high. Another advantage of the high-resistance rotor is that it reduces the stator heating during a change of speed.

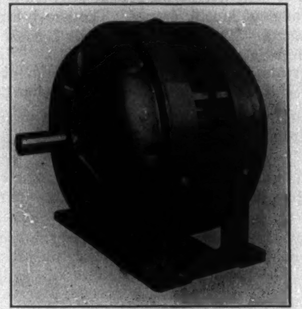

FIG. 1—SQUIRREL-CAGE TYPE ELEVATOR MOTOR

For a low-speed elevator the stator is usually wound for a single speed. For higher speeds the motor is built for two speeds since at high elevator speeds it is more difficult to make accurate landing. In the case of two-speed motors, the high-speed winding is generally used for starting and running and the low-speed for retarding and landing. The speed ratio required for the two windings should be greater the higher the speed of the elevator. Common speed ratios are 2-1, 3-1, 4-1, and 6-1. The high speed usually has four poles or more and the low speed 48 poles or less. A common motor for high-speed elevators has eight poles on the high speed and 48 poles on the low speed, running at synchronous speeds of 900 rev. per min. and 150 rev. per min. respectively on 60 cycles. The speed-torque and current-torque curves of two representative motors are shown in Figs. 2 and 3.

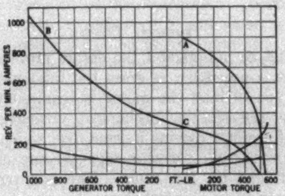

FIG. 2—TORQUE AND CURRENT CHARACTERISTICS OF 3-1 ELEVATOR MOTOR

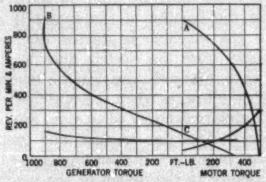

FIG. 3—TORQUE AND CURRENT CHARACTERISTICS OF 6-1 ELEVATOR MOTOR

Performance calculations on the high-speed winding are much simpler than on the low-speed winding. The conventional methods of calculation by the use of the circle diagram are possible only with the higher speeds. With the lowest speeds such as with 48 poles, the con-

---

*Presented at Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

ventional circle diagram cannot be used. The reason is that the stator winding has high resistance and reactance characteristics due to the large number of turns of relatively small wire required. The idle current is practically the same as the starting current. There is a method of using a circle diagram for this type of motor in which diagrams the circle is displaced and tipped from its ordinary position. This method has been described by Behrend and makes use of McAllister's Transformations. But this graphical method has not been found convenient and expeditious for design work. Calculations using the constants of the circuits have proved much less laborious.

These motors are wound for star connection but the leads going to the neutral are brought out of the machine separately instead of being connected inside. This allows the user to insert resistance for starting, if desired, at the neutral point where the voltage between phases is low and the insulation problem in the control is thereby made simple. With this arrangement the wiring arrangement of the control is likewise simplified.

### INERTIA LOADS

In order to understand the design problems in this motor, it is necessary to grasp the fundamental ideas of the type of load the motor is required to handle. Consider the simple mechanical arrangement consisting of a motor driving a drum over which is hung a cable carrying an elevator cage on one end and a counterweight on the other. The counterweight is usually enough to counterbalance the weight of the cage and a certain portion of the capacity load. This portion is usually in the neighborhood of 40 per cent. Thus, with a load of 40 per cent of capacity the weights on the two sides of the drum are equal and the motor has no load except to accelerate the masses and to overcome friction. It might seem that under this condition the motor hasn't much to do, but both theory and practise show that the condition with exact counterbalancing is little different from an unbalanced load in so far as the heating of the motor is concerned. Every time the machine is started the motor must transfer energy from the electric lines to the moving parts and then reabsorb this kinetic energy in connection with the brakes when the machine slows down to stop. During rush hours when stops are being made at nearly every floor this creation and destruction of kinetic energy becomes a dominating factor in the load and consequently in the design of the machine. The energy relations involved in the accelerating and retarding of an induction motor with a pure inertia load are easily derived.

The mechanical power output of the rotor is given by

$$\text{mechanical power output} = K\,\omega\,T$$

Where $\omega$ and $T$ are the angular velocity and the torque respectively and $K$ is a constant depending upon the system of units. From elementary induction-motor theory the electrical power input to the rotor is given by

$$\text{Electrical power input} = K\,\Omega\,T$$

Where $\Omega$ is the angular velocity at synchronous speed. Since the load is inertia only

$$T = \frac{I}{g}\,\frac{d\,\omega}{d\,t}$$

Where $I$ is the *equivalent* moment of inertia of the rotor and is determined by transferring all of the kinetic energy of the moving parts of both motor and connected load to the rotor. The *energy* relations for the rotor during change of speed may then be set up as

$$\text{Mechanical energy output} = \frac{K\,I}{g}\int_{t_1}^{t_2}\omega\,\frac{d\,\omega}{d\,t}\,d\,t$$

$$= \frac{K\,I}{2\,g}\,(\omega_2^2 - \omega_1^2) \qquad (1)$$

$$\text{Electrical energy input} = \frac{K\,I\,\Omega}{g}\int_{t_1}^{t_2}\frac{d\,\omega}{d\,t}\,d\,t$$

$$= \frac{K\,I\,\Omega}{g}\,(\omega_2 - \omega_1) \qquad (2)$$

The expression (1) simply states that the mechanical output of the rotor during change of speed is equal to the change of kinetic energy. The above expressions are general. Their significance will become clear if certain special cases are considered.

### ROTOR EFFICIENCY DURING ACCELERATION

If an induction motor comes up to synchronous speed from standstill

$$\omega_1 = 0 \qquad \omega_2 = \Omega$$

$$\text{In this case rotor output} = \frac{K\,I\,\Omega^2}{2\,g} \qquad (3)$$

$$\text{rotor input} = \frac{K\,I\,\Omega^2}{g} \qquad (4)$$

It is thus seen that

$$\text{Rotor loss} = \text{kinetic energy}$$

This relation is true whatever the rotor or stator resistance and whatever the flux density. Indeed all of these quantities may be variables during the process of acceleration.

### ROTOR EFFICIENCY DURING RETARDATION

In elevator operation the process of retardation from high speed consists of throwing over to the low-speed winding. The low-speed winding is then running above synchronous speed and will act as a generator. It will transfer some of the kinetic energy of rotation back to the line. Reference to the curves in Figs. 2 and 3 will show the situation. With the high speed in operation the elevator with pure inertia load is operating at point *A*. After the shift to low speed it is operating at *B* and the rotor is subjected to retarding torque. The rotor is retarded until it is in low-speed synchronism at *C*.

The energy relations for this process may be derived from expressions (**1**) and (**2**) in which is substituted the new synchronous speed $\Omega/Z$. Also

$$\omega_2 = \Omega/Z \text{ and } \omega_1 = \Omega$$

Substituting in (**1**) and (**2**) there results

$$\text{rotor mechanical output} = \frac{K\,I}{2\,g}\left(\frac{\Omega^2}{Z^2} - \Omega^2\right)$$

$$= -\frac{K\,I}{2\,g}\,\Omega^2\left(\frac{Z^2-1}{Z^2}\right) \qquad (5)$$

$$\text{rotor electrical input} = \frac{K\,I}{g}\;\frac{\Omega}{Z}\left(\frac{\Omega}{Z} - \Omega\right)$$

$$= -\frac{K\,I}{g}\,\Omega^2\left(\frac{Z-1}{Z^2}\right) \qquad (6)$$

The negative signs show that the machine is now a generator with mechanical input, derived from the change in kinetic energy and electric output from the rotor to the stator.

If the rotor electrical output $\frac{K\,I}{g}\,\Omega^2\,\frac{Z-1}{Z^2}$ be divided by the high-speed kinetic energy from expression (**3**) there will result an expression showing the portion of the high-speed kinetic energy which is returned to the stator by regenerative braking. This expression is

$$\frac{\text{energy returned}}{\text{high-speed kinetic energy}} = 2\left(\frac{Z-1}{Z^2}\right) \qquad (7)$$

It is now possible to make up a table showing what becomes of the kinetic energy of the rotor and load when a shift is made to low speed and when after low-speed synchronism is reached mechanical brakes are applied. The unit of energy is the kinetic energy at high-speed synchronism.

TABLE I

| | | | | |
|---|---|---|---|---|
| Z (speed ratio) | 2 | 3 | 4 | 6 |
| Original kinetic energy | 1 | 1 | 1 | 1 |
| Portion returned to stator from (7) | 0.5 | 0.44 | 0.37 | 0.28 |
| Portion lost in mechanical brake | 0.25 | 0.11 | 0.06 | 0.03 |
| Portion lost in rotor winding | 0.25 | 0.45 | 0.57 | 0.69 |
| Rotor loss per cycle | 1.25 | 1.45 | 1.57 | 1.69 |

The last line shows the units of energy going into rotor loss for one complete cycle consisting of starting on high speed, changing to low speed, and applying a brake. If the mechanical brakes be applied and the winding disconnected before low-speed synchronism is reached, they will absorb a disproportionate amount of energy and the portions returned to the stator and lost in the rotor will be reduced.

## STATOR LOSSES

So far, emphasis has been laid upon rotor loss and little has been said concerning stator losses. The reason for this is that with a high-resistance rotor most of the power loss is in the rotor. Once the rotor loss is known for inertia loads the stator loss is not difficult to determine since

$$\frac{\text{Stator loss}}{\text{Rotor loss}} = \frac{\text{stator resistance}}{\text{rotor resistance}}$$

where the rotor resistance is the value after being transformed to the stator.

This relation holds true for any induction motor which has stator resistance and reactance low enough that the total currents in the rotor and stator are substantially equal and opposite. This condition is true for the high-speed winding and also for low-speed windings providing their speed is not too low. The above expression shows the advantage to the stator of the high-resistance rotor in the matter of stator loss on inertia load. The rotor loss is constant no matter what the rotor or stator resistance or the manner of applying voltage to the machine terminals. A high-resistance rotor reduces the stator loss. It is evident that the insertion of resistance in the stator leads for purposes of control has no effect upon the relation given above. The only effect is to spread the change in speed out over a greater time and to incur additional losses in the control resistance.

For those low-speed windings where stator resistances cause the performance to depart from classical circle-diagram performance (roughly below 300 rev. per min. at 60 cycles) energy loss in low-speed stator winding can be easily determined by multiplying the power loss of the stator when running idle by the time the low speed is in operation during each cycle. This is possible because the low-speed current does not vary much over the range of speed involved.

It is thus seen that with the exception noted above, the kinetic energy stored in the load is a measure of the heat developed in both the rotor and stator windings for inertia loads.

As an example of the importance of the load imposed by starting and stopping in comparison with running, consider the case of a certain motor. It is a 6-1 speed ratio and when the rotor is up to speed it alone has 15,200 ft.-lb. of kinetic energy. Couplings and brake drums revolving at the same speed will add possibly 4000 ft.-lb. The cage, with load, and counterweights may add 5000 ft.-lb. more. The total kinetic energy is then 24,200 ft.-lb. Since this is a 6-1 motor the energy transformed into heat in the rotor for a single start and stop will be

$$1.69 \times 24{,}200 = 40{,}500 \text{ ft.-lb.}$$

With capacity load the rotor has an output of 27 hp. and the slip is 16.6 per cent. With this capacity load the motor must run 13.5 sec. on high speed to have an energy loss in the rotor equal to the loss from starting and stopping. At 450 ft. per min. this would mean seven floors of high-speed running; this would mean nine floors between stops. When it is considered that with heavy loads frequent stopping is necessary it is evident that the starting and stopping develop most of the heat in the machine. Since the kinetic energy is a measure of the heat loss in the elevator motor, it is advantageous to keep the kinetic energy as low as possible in order to keep the motor temperature down. Most of the kinetic energy is stored in the rotor of the motor and those parts of the elevator machine which are directly connected to the motor shaft. The energy storage in the more slowly moving parts and in the elevator cage and counterweight are seldom, if ever, greater than 20 per cent of the total, so the rotor and next adjacent parts store about 80 per cent of the kinetic energy.

Quite obviously, then, the rotor and associated parts should have the smallest moment of inertia possible consistent with good design. The rotor lamination should be stacked on a spider to eliminate the weight of lamination that would otherwise run to the shaft. The spider itself can be designed to make a not inconsiderable saving in weight. Welded steel spiders which, in one case, weigh 43 lb. apiece displaced cast iron spiders which weighed 89 lb. apiece. The magnetic circuit and electrical circuits of the rotor should be worked at higher densities of flux and current than is permissible in continuous duty industrial motors in order to keep the mass of the rotor down to low values. In this connection, the elevator builder has his part to do in keeping down inertia losses. He should reduce as much as possible the weight of all moving parts particularly those working at the higher speeds.

The problem of dissipating the heat evolved in the motor is accentuated by the fact that the ventilation is materially cut down owing to the accelerating and retarding features of the service which keep the average speed of the motor at less than one-half of the high speed. It is necessary, therefore, to provide special means for transferring the heat developed to the ventilating air. To this end the areas of all air passages through the machine should be four or five times greater than for standard motors. This has been made possible to large extent by using arc welded steel instead of cast iron for frames. Extra large blower paddles are provided on the rotor to increase the volume of air moved as well as to conduct the heat from the rotor to the air stream. Since most of the heat in the machine is developed in the high-resistance rotor it is important to abstract as much as possible from the rotor without requiring it to cross the air-gap and heat the stator. The stator is provided with ventilating fins which are in the path of the air issuing from the motor. The circumferential fin is set into the stator lamination and draws heat from deep in the laminations. The cross fins span all the laminations and are arc welded in place. See Fig. 1.

The problem of heat dissipation increases rapidly with increase in diameter of the rotor. If we consider comparative designs at the same speed and lamination length we find for the ordinary motor that to a first approximation the various constants vary with the diameter $D$ as listed.

| Torque | Running loss | Moment of inertia | Starting and stopping loss |
|---|---|---|---|
| $D^2$ | $D^2$ | $D^4$ | $D^4$ |

The reason that the moment of inertia varies as the fourth power of the diameter is that the radial depth of the rotor lamination must vary as the diameter. This condition shows that as the diameters of elevator motors are increased in order to get more torque the heating problem due to inertia load gets rapidly more acute—and means for cooling the machine will become a constantly increasing problem.

These motors bear a horsepower rating but this rating is an empirical expression only. The horsepower is generally calculated by assuming the motor to be running at 90 per cent of synchronous speed and developing 40 per cent of the starting torque. A more useful rating is the starting torque in foot-pounds as a torque calculation is more simple and direct than a power calculation. The starting torques available in standard motors range from 10 to 2800 ft.-lb. with empirical horsepower ratings ranging from 1 to 150 hp.

## NOISE ELIMINATION

Noise elimination is of paramount importance in elevator motors. The magnetic hum so characteristic of ordinary induction motors becomes an insidious nuisance in a location where people must live with it. Hotels, apartments, offices, and hospitals demand noiseless operation. The predominant cause of noise in induction motors is the existence of harmonics of both flux and current. Elementary induction motor theory assumes that there is a single sinusoidal field rotating at synchronous speed. It is, however, well known that if the actual distributions of conductors and currents are analyzed according to Fourier's method the field is really composed of a multitude of harmonic fields rotating some forward and some backward. These fields are fairly well damped out by the rotor bars but the damping process requires harmonic currents in the rotor. The interaction of these currents and fields sets up periodic forces which in turn move the rods and teeth enough to produce noise. Pitch or coil span is known to have a vital connection with the production of harmonics and since the 5th and 7th tend to have the greatest magnitudes it is well to keep them as low as possible. This can be done by making the pitch or span equal to approximately 5/6 of a pole pitch. The number of slots per phase per pole is closely connected with the production of harmonics. Here again Fourier's analysis shows considerable improvement in this regard of a motor having two slots per phase per pole over one having a single slot per phase per pole. For this reason one should set two slots per phase per pole as the absolute minimum if one is to have a quiet motor. It is common in general motor practise to use fractional number of slots per phase per pole. This is inadmissible in an elevator motor because the resulting dissymetry produces noise from the harmonics set up.

The requirement of a minimum of 2 slots per pole per phase results in stators with a greater number of slots than is common for the ordinary induction motor of equivalent size. If we consider a 900-150 rev. per min. motor for three-phase and 60 cycles we see that the low speed has 48 poles. This means that the stator has 288 slots where the standard motor of the same size and of course of higher speed, has only 96 slots.

Another persistent source of noise is in slot combinations as between rotor and stator. Every designer of induction motors has had noise troubles from this source which were corrected by changing the number of rotor bars. In this connection it was formerly the custom to select the number of rotor bars by some empirical rule but of late this method has been partially displaced by a more rational and analytical process—having to do with the harmonics set up by the rotor bars. In spite of this advance into less empirical methods this field is by no means conquered and it offers a fertile field for further investigation and report.

## ROTOR SKEW

An interesting problem arose in connection with the skewing of the rotor rods. It is common practise among all manufacturers to skew rotors. This has two effects which it is desired to utilize. The first and most important is that with a properly skewed rotor there are no positions of the rotor where it tends to remain locked in position due to the variation in magnetic reluctance of the air-gap as the rotor is turned. This effect, sometimes known as "cogging", produces pulsations in torque if allowed to become of too great magnitude by improper amount of skew. A second effect desired from rotor skew is to reduce noise resulting from the pulsating torque. Then a third effect forced itself into the problem of design.

It happened that sometimes motors supposed to be identical in every respect showed variations in starting torque much too large to be accounted for by the ordinary variations usually encountered in building induction motors. This occurred for the most part on 48-pole windings. It was found to be due to the variations in skew of the rotor rods. As an example consider a 48-pole stator and a rotor with 90 skewed bars. The design would probably call for a skew of one rotor slot pitch. This skew is

$$\frac{48 \times 180 \text{ deg.}}{90} = 96 \text{ deg. (electrical)}$$

The effect is the same as that due to the distribution of a phase group in the stator over a plurality of slots except here the distribution is *continuous* instead of discontinuous as in the stator. To carry the comparison further consider the voltages generated in the stator and skewed rotor by a sinusoidal rotating magnetic field. In the stator if there are two slots per phase per pole each phase voltage generated in the stator consists of two components separated by an angle which is 30 deg. for three-phase and 45 deg. for two-phase. (See Fig. 4.)

$$\text{The distribution factor} = \frac{E_2}{2\,E_1}$$

The distribution factor may be defined as the actual voltage generated divided by the voltage that would be generated if the winding were concentrated.

In the case of skewed rotor rods it will be seen that each elementary length of rotor rod has an infinitesimal voltage generated in it which is out of phase with that generated in the next adjoining element. The voltage generated in the rod is the integrated voltage of these elementary lengths. Vectorially we have the elementary voltages forming the arc of a circle and the sum is the chord. Hence, the voltage actually generated in a rotor rod is less than would be generated if the rod were without skew.

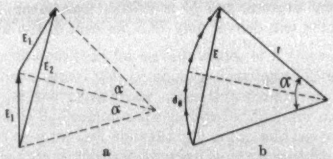

FIG. 4—VOLTAGES IN STATOR AND SKEWED ROTOR

a. Stator voltages, showing effect of distributing the winding in two slots per phase per pole. $E_1$ = voltage in ½ of 1 phase. $E_2$ = phase voltage. This effect is similar to the effect got in the squirrel-cage rotor by skewing the rotor bars.

b. Rotor voltages. With a skewed rotor bar the elemental lengths of the bars have infinitesimal voltages generated in them which are *out of phase* just the same as the voltages induced in adjacent slots of the stator are out of phase. The elemental vector voltages plotted end-on-end lie along the arc of a circle. The sum is the chord.

$$\text{"Skew factor"} = \frac{E}{\int_{\alpha=0}^{\alpha=\alpha} d\,e} = \frac{2\,r\,\text{Sin}\frac{\alpha}{2}}{r\,\alpha} = \frac{2\,\text{Sin}\,\frac{\alpha}{2}}{\alpha}$$

$$\text{The ratio } \frac{\text{actual voltage generated per rod}}{\text{voltage for unskewed rod}} \text{ might be}$$

called "skew factor."

It will be obvious that this ratio is independent of the slip and the result is that the torque is

$$\text{Torque with skew} = S^2 \times \text{torque without skew}$$

since the torque is measured by the rotor input and the rotor input varies as the square of the rotor voltage at any particular slip. An alternative way of satisfying oneself of the square relation expressed above is to consider that since the voltage induced in a skewed rod is $S$ times the voltage for an unskewed rod the current for skewed and unskewed rods will be in the same ratio. Now the current flowing in a skewed rod placed in an unskewed magnetic field will have elemental torques out of phase in the same manner that the voltages were out of phase. Fig. 4 can be used to illustrate the integration of elementary torques. Hence, the factor $S$ enters a second time.

In Fig. 5 the skew factor $S$ is plotted against skew in electrical degrees. The square of $S$ is also plotted. When we refer to the latter curve we can see the importance not only of using this skew factor in our calculations, but also the importance of keeping variations of skew in practical manufacture down to certain narrow limits. As an example, suppose a rotor has 90 rods and is 20 in. in diameter. If it is operating in a 48-pole field with a skew of exactly one slot pitch we find the 100 per cent skew to be 0.70 in., the skew angle is 96 electrical degrees, and $S^2$ is 0.785. This means that the motor will deliver only 78.5 per cent of the torque it would deliver if it were designed without skew. The effect of inaccurate skew can be shown in tabular form where "per cent skew" means the percentage of 1 slot skew.

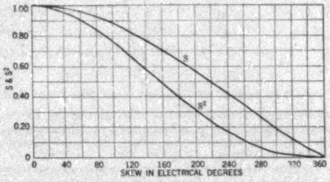

FIG. 5—SKEW FACTOR PLOTTED AGAINST SKEW

$$\text{"Skew factor" } S = \frac{360 \text{ Sin } \frac{\alpha}{2}}{\pi\,\alpha} \quad \text{where } \alpha \text{ is skew in electrical degrees}$$

| Per cent skew | Inches skew | Skew angle | $S^2$ |
|---|---|---|---|
| 80 per cent | 0.56 | 77 deg. | 0.82 |
| 100 per cent | 0.70 | 96 deg. | 0.785 |
| 120 per cent | 0.84 | 115 deg. | 0.71 |

Thus, we see if the skew is held only approximately that the torque of the machine may vary by

$$\frac{0.82 - 0.71}{0.785} = 14 \text{ per cent}$$

This variation is too large to be neglected.

## STATOR COPPER BALANCE

In the case of a two-speed motor with two separate windings the question of the proper balance of copper section between the two windings is of utmost importance. If this is not carefully attended to it will be found that out on the job one winding will be running hot while the other is cool. It is obvious that the proper division of slot area between the two windings depends upon the duty cycle of the elevator and the relative service demanded from the two windings. A little calculation of the losses in the two windings will show that the minimum amount of heat will be evolved in the stator windings when the ratio of the copper cross-sections of the two windings is equal to the ratio of energy (not power) losses in the two windings. That is,

$$\frac{A_1}{A_2} = \frac{Q_1}{Q_2}$$

Where $A$ and $Q$ represent the cross-sectional area of copper in the slot and the energy losses respectively and the subscripts identify the winding with which the particular quantity is associated.

While there are two stator windings there is only one rotor winding and it is necessary to build this rotor winding so that it will have the correct resistance for both speeds. The losses in the rotor winding occur in two parts of the circuit—in the bars and in the end rings. The ratio of these losses is given by the expression

$$\frac{\text{Ring loss}}{\text{Bar loss}} = \left(\frac{0.635\,N}{P^2}\right) \times \left(\frac{D}{L}\right) \times \left(\frac{A_B}{A_R}\right) \times (K)$$

Where $P$ Number of poles
$N$ Number of rotor bars
$L$ Length of rotor bar
$D$ Mean diameter of end ring
$A_R$ Cross-sectional area of the end ring
$A_B$ Cross-sectional area of one bar
$K$ Ratio of conductivities of material in bar and material in ring (Unity for bar and ring of same material)

This expression shows that in a two-speed motor with a speed ratio of 6–1 the proportion of ring loss to bar loss on the low speed is 1/36 of its value on the high speed.

In one such rotor the ratio of ring loss to bar loss is 0.292 for the high-speed condition. On the low speed this ratio falls to 0.008. In this case the ring loss is negligible on low speed. It is then obvious in this case that the proper method of getting the desired rotor resistance on both speeds is to design the rods for low-speed operation and design the rings to go with these rods for proper high-speed design.

## TRANSFORMER EFFECTS IN TWO-SPEED STATORS

The design of the stator winding in a two-speed two-winding motor is subjected to limitations which are not present in a single winding motor because of the transformer effects between the windings. When one winding is in operation the revolving flux cuts the conductors of the other winding and sets up voltages in them. Great care must be taken that these induced transformer voltages do not set up parasitic currents in the idle winding and give trouble due to overheating and noise. In certain speed combinations, even though internal parasitic currents are eliminated, voltages appear at the terminals of the idle winding which may cause trouble with connected control apparatus.

When one winding is operating it is obvious that every conductor in the idle winding has the same e. m. f. induced in it as is induced in a conductor of the operating winding. The problem is to so connect each winding that these e. m. fs. either cancel each other out or at least do not set up parasitic currents when the windings are out of use and at the same time to so connect them that the operation will be proper when in use.

A full account of the analysis necessary to cover the subject of elimination of harmful transformer effects is long enough to form a paper in itself so the present paper will limit itself to brief explanations of methods, followed by tabulated results which would be obtained by extensions of the methods.

## ELIMINATION OF CIRCULATING CURRENTS IN THE HIGH-SPEED WINDING

We will first concern ourselves with transformer effects in the high-speed winding induced by operating the low-speed winding.

*Correction by High-Speed Coil Pitch.* If the speed ratio is, for instance, 2 it is evident that if the high-speed coils are wound full pitch the two conductors forming a turn will have e. m. fs. induced in them 360 deg. apart and the turn e. m. f. will be zero. If the speed ratio is 3 the turn e. m. f. will be zero if the high-speed pitch is 2/3 or 4/3. We may generalize and say if the speed ratio is $Z$ the e. m. f. per turn of the high speed will be zero if the

$$\text{high-speed pitch} = \frac{2}{Z}, \frac{4}{Z}, \frac{6}{Z} \text{ etc., where } Z \text{ is}$$

always taken $> 1$ and may be fractional or integral. By using this pitch, the high-speed winding may then be connected any way desired without further thought to transformer effects in it. The designer, however, may not wish to use the coil pitch demanded by this type of correction because it may be a pitch conducive to noise from harmonics or it may be a pitch not physically attainable with the number of slots at his disposal. He must then accept turn voltages other than zero and expect to annul them in coil or group connections.

*Correction in the Phase Group.* In case the induced voltage per turn is not zero, the voltage per coil will be the turn voltage multiplied by the number of turns. The coils which make up a phase group are equally distributed over 60 electrical deg. in an ordinary three-phase winding. When the low speed is operating this 60 deg. is changed to 60 $\times Z$ deg. This condition can be very simply shown by vectors in Fig. 6. The vectors $A$, $B$, and $C$ represent the voltages induced in adjacent high-speed coils of the same phase group when the high speed is operating. These coils are always connected in series so that the group voltage is the vectorial sum. When the low speed is operating the span that was 60 deg. now becomes 60 deg. $\times Z$ because the electrical degrees between adjacent coils is $Z$ times what it was before. This vectorial condition is shown in Fig. 7.

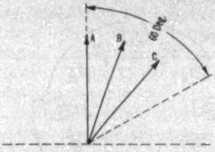

FIG. 6—VOLTAGES INDUCED IN HIGH-SPEED WINDING WHEN HIGH-SPEED WINDING IS OPERATING

In a three-phase high-speed winding the voltages $A$, $B$, $C$ generated in the various slots of a phase group are spread over 60 electrical degrees *only* when the high speed is in operation. When the low speed is operating these vector voltages are spread over 60 $\times Z$ deg.

It is obvious that for certain values of $Z$ the vectors in a phase group will be equally distributed over 360 deg. In the three-phase case this condition occurs when $Z = 6$, a common speed ratio for elevator motors. In this case the coil voltages in a group add up to zero and the groups may be connected in any desired manner without reference to transformer effects. By extension of this reasoning we may summarize on corrections in the phase group.

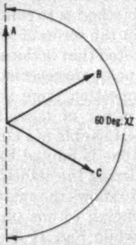

FIG. 7—VOLTAGES INDUCED IN HIGH-SPEED WINDING WHEN LOW-SPEED WINDING IS OPERATING

The vector voltages generated in a high-speed group are spread over 60 $\times Z$ electrical degrees when the low speed is operating. The transformer voltage in a high-speed group is then $A + B + C$. In case 60 deg. $\times Z$ is a multiple of 360 deg., $A + B + C = 0$.

Group voltages on the high speed will be zero for
3 phase (60 deg. distribution) when $Z = 6$, 12, or any multiple of 6
3 phase (120 deg. distribution) when $Z = 3$, 6, or any multiple of 3
2 phase when $Z = 2$, 4, or any multiple of 2

*Correction by Group Connections.* There occur many cases in two speed-windings where neither the turn voltage nor the group voltage can be made zero, the latter for those speed ratios which do not occur in the above table. In those cases where one has a group transformer voltage in the high-speed winding with low-speed operating one must be careful that any internal parallel connections are not the seat of parasitic circulating currents due to these group voltages. Suppose one has a three-phase motor with four poles on the high speed and 16 on the low speed in which the turn voltage has not been made zero by correction in coil pitch. There will then be transformer voltages in the 12-phase groups. Suppose the designer wishes to connect the four groups of a phase two series two parallel. There are two common ways of making this connection in single-speed motors—one is to connect the corresponding groups from adjacent poles in series and then parallel two such series of adjacent poles as in Fig. 8. The other method is to connect alternate poles in series and parallel the series of alternate poles as in Fig. 9. It is to be noted that in the adjacent connection the even numbered poles are reversed in the series while in the alternate connection there is no reversal inside the series. While either of these series-parallel connections would be permissible in a single-speed winding, it will be seen that one is limited to the adjacent connection when considering the transformer effect from a 16-pole field. Fig. 10 shows the arrangement of the four group voltages belonging to one phase when the high speed is operating while Fig. 11 shows the new array of vectors when the low-speed flux acts upon the high-speed winding. The angular distance between adjacent vectors has been increased from 180 deg. to 4 × 180 deg. because 4 is the speed ratio.

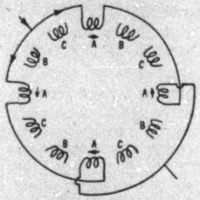

FIG. 8—STATOR CONNECTED SERIES-PARALLEL WITH ADJACENT POLES IN SERIES

Note that adjacent poles are reversed

The adjacent connection gives 1 − 2 in series in one leg of the parallel connection with 3 − 4 in the other. Here we see that 1 − 2 has zero transformer voltage as has also 3 − 4. There will then be no trouble with circulating currents between the two legs of the parallel connection. On the other hand, the alternate connection shows 1 + 3 paralleled with − 2 − 4. The vector arrangement with transformer voltages is shown in Fig. 12. This connection causes all the transformer voltages to add up in phase around the local parallel circuit and the circulating current will make the connection impossible.

Extending this analysis a table is now given which shows the number of poles which must be in series to make transformer voltage zero in a series leg and thus eliminate circulating currents in the high-speed winding with the low-speed operating.

TABLE II

| Z | Adjacent connection | Alternate connection | |
|---|---|---|---|
| 2, 4, 6, etc. | 2 | Impossible | Number of poles in series must be a multiple of number shown to eliminate transformer voltages in series leg of parallel connection. |
| 3/2, 5/2, 7/2 etc. | 4 | 2 | |
| 4/3, 8/3, 10/3 etc. | 6 | 3 | |
| 5/3, 7/3, 11/3 etc. | 3 | 3 | |
| 5/4, 7/4, 9/4 etc. | 8 | 4 | |
| 6/5, 8/5, 12/5 etc. | 10 | 5 | |
| 7/5, 9/5, 11/5 etc. | 5 | 5 | |

It will be noted that the foregoing tabulation does not contain any speed ratios where *Z* is an odd number. The reason for this is that if the speed ratio is an odd number, it is impossible to connect the series circuits so that the voltage in a series leg is zero. It will be found, however, that with odd speed ratios the coils in the high-speed winding may be connected in any standard manner because it will always occur that the transformer voltage in one leg of a parallel connection is equal to the transformer voltage in the other leg (or legs) of that same phase and thus no circulating current will flow. (See Fig. 13.) This does mean, however, that there is a transformer voltage generated in each phase which voltage appears at the terminals of the machine. This fact may have a vital bearing on the type of control used with the motor.

## ELIMINATION OF CIRCULATING CURRENTS IN LOW-SPEED WINDING

A little thought will show that it is impossible to annul the transformer voltage in the low-speed winding by the first two devices used in the high-speed winding, that is, by choosing a particular coil pitch or by having the voltages in a group add to zero. The only recourse in eliminating trouble in the low-speed winding is to make sure that circulating currents cannot occur in any parallels by so connecting the proper poles in series that

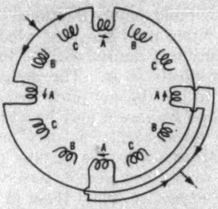

FIG. 9—STATOR CONNECTED SERIES-PARALLEL WITH ALTERNATE POLES IN SERIES

the transformer voltage of a series leg is made zero just as was done in the high-speed winding. The following table will show the proper number of poles to be connected in series to obtain zero leg voltage for the various speed ratios and the two commonest type of connection, that is, adjacent poles in series and alternate poles in series.

TABLE III

| *Z* | Adjacent connection | Alternate connection | |
|---|---|---|---|
| 2 | 4 | 2 | Number of poles in series must be a multiple of number shown to eliminate transformer voltages in series leg of parallel connection. |
| 3 | 3 | 3 | |
| 3/2 | 6 | 3 | |
| 4, 4/3 | 8 | 4 | |
| 5, 5/3 | 5 | 5 | |
| 5/2, 5/4 | 10 | 5 | |
| 6, 6/5 | 12 | 6 | |
| 7, 7/3, 7/5 | 7 | 7 | |
| 7/2, 7/4, 7/6 | 14 | 7 | |

FIG. 10

FIG. 11

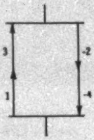

FIG. 12

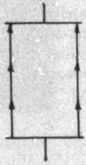

FIG. 13

FIG. 10—GROUP VOLTAGES IN HIGH-SPEED WINDING WHEN HIGH-SPEED WINDING IS OPERATING

These are the four group voltage in one-phase of a four-pole stator. The distance between successive voltages is 180 electrical degrees.

FIG. 11—GROUP VOLTAGES IN HIGH-SPEED WINDING WHEN LOW-SPEED WINDING IS OPERATING

When the high-speed winding of Fig. 10 is subjected to the low-speed field of 16 poles the successive polar voltages are 4 × 180 deg. apart because 4 is the speed ratio

FIG. 12—LOCAL CIRCULATING CURRENTS SET UP IN HIGH-SPEED WINDING WITH SERIES-PARALLEL CONNECTION

These currents are induced by transformer effects from the low-speed winding

FIG. 13—TRANSFORMER VOLTAGES SET UP IN HIGH-SPEED WINDING WHEN THE SPEED RATIO IS AN ODD INTEGER

No circulating currents can occur but induced transformer voltages do appear at the terminals of the high-speed winding

As an example of the use of these tables, suppose it is wished to build a 3-phase motor with synchronous speeds of 900 and 225 rev. per min. This is a 4 – 1 ratio. There will be 8 and 32 poles. If there are 192 slots there will be 24 slots per pole on the high speed and 6 on the low speed.

Transformer voltage in the high speed may be eliminated at the start by making the pitch $P = Z/4$ which in this case is $P = 1$ since $Z = 4$. But, it may not be desired to wind this high speed with full pitch due to harmonics or due to the fact that the designer desires a shorter pitch to obtain the proper flux density. He will then have transformer voltages in the coils. He will also have transformer voltages in the groups and the question remains how to connect the groups to obtain zero leg voltage. Table II shows that if he connects adjacent poles in series only two poles to a series leg are needed although any multiple of two may be used. He may then connect the high-speed groups

| | |
|---|---|
| 2 series | 4 parallel |
| 4 series | 2 parallel |
| 8 series | |

He also sees that no parallel connection is possible if he connects alternate groups in series.

Turning now to the low-speed winding, he sees the limitations from Table III. This table tells that circulating currents in parallels will be eliminated if he has multiples of eight poles in series with the adjacent connection and multiples of four poles in series with the alternate connection. We may then connect the 32 poles as follows:

| Adjacent Connection | | Alternate Connection | |
|---|---|---|---|
| 8 series | 4 parallel | 4 series | 8 parallel |
| 16 series | 2 parallel | 8 series | 4 parallel |
| 32 series | | 16 series | 2 parallel |
| | | 32 series | |

## CONCLUSION

The growing demand for and use of a-c. elevators is natural since d-c. is more expensive to produce and distribute than a-c. In case a-c. only is available in a given locality it is necessary to install conversion apparatus in addition to the elevators in order to operate d-c. elevators. There is every indication that the use of a-c. elevators is in its infancy. As the use is extended the design problems and their solutions which are the subject of this paper will represent, it is hoped, a substantial start in the more economical use of electric power and invested capital in this particular field.

# Electric Welding of Pipe Lines

BY J. D. WRIGHT[1]
Associate, A. I. E. E.

*Synopsis.—This paper outlines the process of manufacture of steel pipe from flat rolled steel plates by automatic metallic arc welding. Data are given showing the physical and chemical analysis of the plate, the weld, and the welding wire, as well as the speed of welding and electrode and power consumption.*

* * * * *

THE economies which have been effected in many manufacturing operations during the past few years by the adoption of electric arc welding for manufacturing as well as for tool repair have been so outstanding as to command the attention of all industries.

In many cases, the reduction in cost has been accompanied by a distinct improvement in quality, so that in these days of increasingly keen competition, no manufacturer marketing a product in which fabricated metal parts are, or might be used, should fail to make a thorough study of the possibilities of electric welding.

One of the newer applications of automatic arc welding is in the fabrication of pipe from flat rolled steel plates. It is particularly applicable to the larger sizes of steel pipe which heretofore have been made either by riveting, by the lock-bar process, or by the hammer weld process. The interest aroused by several successful installations of lines of pipe fabricated by the electric arc welding process has been very widespread, and it is the purpose of this paper to discuss the present state of the art as exemplified by a recent installation.

The example selected is the process employed for fabricating the pipe for a line approximately eight miles long, to convey water from the Provin Mountain Reservoir to the City of Springfield, Massachusetts. From the reservoir to the west bank of the Connecticut River, a single line of 54-in. and 48-in. diameter pipe is used. Two lines of 36-in. diameter each are laid under the Connecticut River, and from its east bank a single line of 48-in. and 42-in. pipe connects with the present distribution system of the City of Springfield. The thickness of the plate used in the pipe varies from 5/16 to 1/2 in.

## TESTS OF WELDED JOINTS

Before bids on welded pipe were submitted, tests were made to determine the strength of the welded joint and a definite procedure was worked out to insure thoroughly reliable and uniform results.

The plates used for the tests were of fire-box steel with tensile strength between the limits of 52,000 and 62,000 lb. per sq. in., as specified by the Engineer of the Board of Water Commissioners. The following shows typical analysis and physical properties of the plate steel:

| | | | |
|---|---|---|---|
| Carbon...... | 0.20 per cent | Yield point— | 35,450 lb. per sq. in. |
| Manganese... | 0.40 | Tensile strength | 57,500 lb. per sq. in. |
| Phosphorus .. | 0.015 | Per cent elongation | 31.5 |
| Sulphur...... | 0.029 | Per cent reduction of area | 56.3 |

Sections 3 in. wide by 48 in. long were sheared from ½-in. plate, and the sections beveled on one 48-in. side as shown by Fig. 1. Two sections were then welded together using the multiple arc process. This will be described in greater detail later. Two beads were deposited, the first with 3/16 in. G. E. type "F" welding electrode using 300/320 amperes at an arc voltage of 18/22, and the second with 3/16 in. G. E. type "B" electrode using 320/360 amperes and 18/22 volts. The welding was done at a speed of approximately 4½ in. per minute.

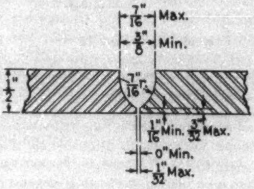

FIG. 1—DIMENSIONS OF BEVEL FOR WELDING ½-IN. PLATES

The following table shows chemical analysis of the two welding electrodes:

| | G. E. type "B" | G. E. type "F" |
|---|---|---|
| Carbon...................... | 0.10 max. | 0.13/0.18 |
| Manganese.................. | 0.25/0.45 | 0.40/0.60 |
| Sulphur...................... | 0.045 max. | 0.03 max. |
| Phosphorus.................. | 0.03 max. | 0.45 max. |
| Silicon...................... | Trace | Trace |

Type "F" is a solid wire to which a special treatment is given to insure a uniform flowing quality. Type "B" has a center metallic core surrounded by a layer of flux, the whole being incased in a metallic sheath.

The welded plates were cut into strips 1½ in. wide and tested for tensile strength in a standard testing machine. The following results are typical of many specimens:

---

[1] Industrial Engineering Dept., General Electric Company, Schenectady, N. Y.

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

| Specimen | Tensile strength lb. per sq. in. | Failure |
|---|---|---|
| 1 | 56,700 | Weld |
| 2 | 61,700 | Weld |
| 3 | 60,200 | Steel |
| 4 | 61,870 | Steel |
| 5 | 55,700 | Weld |
| 6 | 60,600 | Steel |

Other specimens were subjected to various bend tests to check the ductility of the weld.

Fig. 2 shows very clearly the metal deposited by the first and second arcs and the zone in the plate stock into which the heat of the weld has penetrated. Photomicrographic studies of the grain structure of the steel in the weld and adjoining plate show total lack of a definite line marking the transition from the weld to the plate, and no evidence whatever of any injury to the plate, owing to heat of the weld.

FIG. 2—DEEPLY ETCHED SECTION OF MULTIPLE ARC WELDED ½-IN. PLATE

FIG. 3—36-FT. PLATE PLANER WITH TWO PLATES IN POSITION FOR MACHINING BEVEL ON 30-FT. SIDE

## MANUFACTURE OF PIPE

The pipe for the Springfield water line is made in 30-ft. lengths from two 30-ft. plates which are bent into half circles and automatically arc welded together. Some consideration was given to welding of the circumferential joints in the field, but because of considerable opposition, it was decided not to do this on this particular job, and the 30-ft. sections are riveted together. To provide for this the plates are sheared so that the pipe diameter increases slightly from one end to the other, thereby permitting the small end of one section to fit into the large end of the next section an amount required for the riveted joint.

FIG. 4—36-FT. BENDING ROLLS FORMING 30-FT. HALF SECTION OF 48-IN. PIPE

The first operation in the manufacture of the pipe after the flat plates have been sheared to size is to bevel the sides accurately as shown in Fig. 1. This is done simultaneously on two plates on the plate planer shown in Fig. 3. On each plate, two lines are then scribed, each parallel to the upper edge of the bevel and ¾ in. from it.

The plate is then taken to the bending rolls, (Fig. 4), and by means of a special jig, the two 30-ft. edges are bent to the proper radius. The whole plate is then formed into a true half circle. Next the two halves of the pipe are placed in a specially designed frame, (Fig. 5), and tack welded together approximately every 16 in. on the inside by hand. After the raised portions of the beads are removed by grinding, the pipe is placed in the automatic welding machine, (Fig. 6).

FIG. 5—FRAMES OF SPECIAL DESIGN SUPPORT THE TWO 30-FT. HALF SECTIONS OF 48-IN. PIPE WHEN BEING TACK WELDED BY HAND FROM THE INSIDE

## PIPE WELDING MACHINE

The pipe welding machine consists essentially of three horizontal beams, two above and one below.

Enclosed in the lower beam and extending throughout its full length are several sections of fire hose to which compressed air can be admitted. On the hose rests a series of plungers which in turn supports a "backing-bar," the latter being fitted with a flat copper chill bar approximately two inches wide. Application of compressed air causes the hose to expand, thereby raising the plungers, and the copper strip in the backing-bar is pushed up against the under side of the joint at a pressure of 200 lb. or more per running inch. The backing-bar is also provided with an insulated conductor which forms part of the return circuit for the welding current. By shunting the proper amount of current through this bar when the pipe is being welded, the magnetic disturbances of the arc can be very effectively controlled.

Fig. 6—End View of 36-Ft. Pipe Welding Machine Showing 30-Ft. Section of 48-In. Pipe Ready for Automatic Arc Welding of Longitudinal Seam

Fig. 7—36-Ft. Pipe Welding Machine Showing Two Travel Carriages Each With Two Welding Heads for Automatic Welding of Pipe by Multiple Arc Process

To the lower side of the upper beams of the machine are attached two copper jaws spaced approximately two inches apart and the pipe is placed in the machine so that the joint to be welded is located centrally between these two copper jaws and directly over the copper strip in the backing-bar.

The multiple arc welding process previously mentioned employs two arcs, one following about eight inches behind the other. The two automatic welding heads, used to feed the wire, are mounted on a single motor driven adjustable speed travel carriage, (Fig. 7), which moves the heads along the work at the proper welding speed.

When work was first started on the manufacture of the pipe for the Springfield line, only one travel carriage with two welding heads was used. This carriage, of course, traveled the full length of each 30-ft. seam. A little later, a second travel carriage with two more heads was added. Welding was then carried on simultaneously with four arcs, one carriage starting at one end and the other at about the middle of the seam. This reduced the welding time per pipe by about 50 per cent. It is expected that a third carriage with two more heads will soon be added, each pair then welding about one-third the total pipe length with corresponding reduction in welding time.

Fig. 8—48-In. Pipe, 30 Ft. Long Fabricated From Two ½-In. Plates by Automatic Arc Welding Undergoing Hydrostatic Pressure Test of 240 Lb.

After one seam is completely welded, the pneumatic clamp is released and the pipe is rotated to bring the second joint into position for welding.

## SPEED OF WELDING; ELECTRODE AND POWER CONSUMPTION

The speed of welding attained by the multiple arc process with two welding heads on ½-in. plate is about 22½ ft. per hour. Using approximately 380 amperes on the first arc and 330 amperes on the second, the total consumption of 3/16-in. electrode is from 0.8 to 0.85 lb. per foot of weld. These welding currents are somewhat different from those used when the test plates were welded, but were found to give better results on the joint between the two sections of pipe. Current for each pair of welding heads is obtained from a 1000-ampere 1-hr. rated constant potential welding generator driven by an induction motor. The power consumed is approximately 2.15 kw-hr. per foot of weld on ½-in. thick plate.

### INSPECTION AND TESTS OF WELDS

At the request of the inspector, test plates having a bevel as specified for the pipe joints are placed in the machine and welded under the same conditions as the pipe itself. These plates are then cut into specimens and tested.

The extent to which the weld is reinforced, that is, its height above the surface of the plate, is usually from 1/16 to 1/8 in. The minimum and maximum values permitted by good practise are 1/32 and 3/16 in. respectively. The weld bead must not be less than 5/8 in. nor more than 1 in. in width and must also be central within 1/16 in. between the lines scribed on the plate each side of the joint. Any holes which are seen on the top surface of the deposited metal are carefully chipped and if they extend below the surface of the plate, the spot is rewelded by hand. The edges of the bead are also examined to see that the weld metal is thoroughly fused along the top of the plate. Any cracks or hollow spots are chipped and rewelded by hand.

FIG. 9—30 FT. SECTION OF 48-IN. PIPE ABOUT TO BE LOWERED INTO ELECTRICALLY HEATED VERTICAL DIPPING TANK TO RECEIVE PROTECTIVE COATING OF COAL TAR PITCH VARNISH

FIG. 10—LAYING OF STEEL PIPE LINE FOR SPRINGFIELD, MASS., WATER SUPPLY. 30-FT. LONGITUDINAL JOINTS ARE AUTOMATICALLY ARC WELDED. CIRCUMFERENTIAL JOINTS MADE IN THE FIELD ARE RIVETED

To determine the amount of penetration, the under side of the welded joint is carefully examined. It is necessary that the metal be so thoroughly fused that no crack can be seen between the edges of the plate.

After the welded pipe has been given a careful visual inspection and any defects rewelded, it is placed in the testing machine, (Fig. 8), and subjected to the following hydrostatic pressures in pounds per square inch:

| Thickness of pipe in inches | 5/16 | 3/8 | 7/16 | 1/2 |
|---|---|---|---|---|
| 66-in. pipe | .. | 160 | .. | .. |
| 54-in. pipe | 135 | 160 | 187 | 213 |
| 48-in. pipe | .. | .. | 210 | 240 |
| 36-in. pipe | .. | .. | .. | 320 |

### DIPPING AND LAYING THE PIPE

The rivet holes are then punched in each end of the pipe after which it is thoroughly cleaned and dipped vertically in an electrically heated tank of coal tar pitch varnish, (Fig. 9). The pipe is submerged in the bath long enough to heat the metal uniformly to the temperature of the bath. It is then removed and suspended in a vertical position until the coating has drained and set.

The pipe is then ready for transporting to the field and laying in the trench, (Fig. 10). After the pipes have been properly placed and connected by temporarily bolting, the circumferential joints are riveted and caulked. The middle portion of each length of pipe is then backfilled but the field joints are left exposed until the line has been tested for tightness.

### CONCLUSION

At the time this paper was written, approximately three miles of pipe had been delivered to the field, and its installation in the trench was progressing rapidly.

The advantages gained by the electric welding of pipe as compared with other methods of manufacture are a very substantial reduction in cost and a superior finished product. The reduction in cost is secured not alone by the decreased weight of steel required but also by a reduction in the cost of the actual work of fabricating the pipe.

Owing to the smooth interior of the welded pipe as compared with the riveted pipe, the resistance to flow is decreased. The circumferential joints are made more easily with welded pipe because of uniform wall thickness whereas with riveted pipe the wall is of double thickness at the riveted joint. The joining of the ends of pipe made by the lock bar process is rendered difficult owing to the presence of the bar.

Arc welded pipe is also invading the field of lap welded pipe produced by the lap weld mills because of the fact that the thickness of the wall of the latter is fixed and often times the pressures are such that much lighter arc welded pipe can be used with consequent reduction in the cost of the line.

## Discussion

**J. F. Lincoln:** Mr. Wright's paper is extremely interesting because it brings out a second successful method for doing this sort of work by the electric arc.

The outstanding example of pipe welding up to this time is the Mokelumne River line, 90 mi. in length and containing 78,000 tons of steel. This line has been completed now for some months. This was done with the carbon-arc process instead of the metallic-arc process as is the case in this smaller line described by Mr. Wright.

It is interesting to compare the results as actually obtained in the Mokelumne River line and that described by Mr. Wright. The steel used in both cases was identical—the tests made of the specimens would show approximately the same results.

The welding speed per arc is slightly higher in the case of the Mokelumne River line by not more than 20 per cent. The cost of doing the welding is somewhat less in the case of the Mokelumne River line because of higher speed, because of cheaper filling material, and because of less power used.

In the case of the Mokelumne River line the hydrostatic tests were approximately 60 per cent higher than in the case of the line described. There was also added, in the case of the Mokelumne River line, a hammer test which is much more severe than the hydrostatic test. This hammer test was applied with a tensile stress on the metal itself in excess of 22,500 lb., and an ultimate test running up to a maximum of 28,000 lb., the tensile test in this case being nearly double that used in the line described.

There has been a good deal of progress made in the application of carbon-arc welding since the manufacture of the Mokelumne River line. Since that time the new development of the "electronic tornado" has more than doubled speeds, has eliminated practically all tendency to porosity which heretofore was present in all cases on both the carbon and metallic electrode welding of thick plate, and it has practically eliminated any necessity for repairing. Welding speeds of a single head in excess of one foot per minute on half-inch plate, and with double heads welding speeds of double that, have been obtained. The welds can be bent flat on themselves without rupture and the ductility of the weld metal is fully as great as the ductility of the plate itself.

I think it is safe to say that as far as the welding is concerned in the manufacture of pipe, all necessary development has been done. There is still much to be desired in the planing, crimping, rolling, and assembly of the plates before welding, which progress will enormously reduce manufacturing costs.

At the present time it probably is true that the cost of welding of the pipe itself is less than 1 per cent of the total cost of the pipe, so that any further progress in welding cost reduction is of little moment compared to the cost reduction possible in the operations other than welding.

**J. C. Lincoln:** The pipe described in Mr. Wright's paper has one end larger than the other so the small end will telescope into the larger end and the ends are riveted as described in the paper. I imagine the inside ends are probably flat-riveted so as to decrease the eddy that would result from the ordinary round-head rivet.

In any case there will be a very considerable eddy at the joint. The metal is $\frac{3}{8}$ or $\frac{1}{2}$ in. thick and all around the pipe there is bound to be an eddy. Mr. Day of the United States Reclamation Service was telling of difficulty which he experienced where eddies were encountered in pipe, and Mr. Imlay of the Niagara Falls Power Company says they have had the same difficulty at Niagara Falls. Where there is a severe eddy, apparently a chemical action takes place, eating out the pipe at that point. In the case Mr. Day described to me, a cast-iron pipe 2 in. thick is corroded so that it has to be replaced or repaired in the very near future.

Mr. Imlay said that on their wheels at Niagara Falls repairs of the same sort had to be made as one of the regular upkeep operations.

It seems to me that is a possible criticism of this method of joining pipe though that has nothing to do with Mr. Wright's paper. It won't be very long, I think, before pipe will be joined, not by riveting, but by welding, and if the pipe is joined by welding there will be no special trouble in making a butt weld in which the ends of the pipe will be beveled and so welded as to leave the inside of the pipe smooth and thus avoid this eddy.

**R. E. Barnard:** I am chief engineer of the Hardesty Manufacturing Company of Denver, manufacturing electric-arc-welded pipe. The particular defect in riveted pipe called to your attention by Mr. Lincoln constituted the main reason for our making electric-welded pipe instead of riveted. In order to eliminate erosive action at the joint we have for several years made a special type of slip-joint pipe in which a collar is electrically welded to one end of a constant-diameter tube and this collar forms the bell into which the spigot end of the abutting section is driven. The result is a smooth interior pipe of the slip-joint type and eliminates the particular destructive action to which reference has been made. We have just completed near Yoder, Wyoming, an electric-arc-welded line entirely field-welded. It is 72 in. in diameter, $\frac{1}{4}$ in. thick, and made with field joints butt-welded. The plates were 6 ft. long, and the field sections 12 ft. long.

The line is about 900 ft. long and has two elbows in the vertical plane, each of about seven degrees deflection. The only expansion joints in the line are at the ends where special transition sections are imbedded in the inlet and outlet.

This 72-in. pipe is made by very nearly the same process as described in the paper, except that the plate edges are not beveled. The quarter-inch plate, not beveled, is fused through with the Lincoln type of machine without difficulty. For making the longitudinal seam we use the automatically controlled and driven Lincoln arc operating over a clamp similar to the one shown in the paper, only not so large. Circumferential seams are automatically welded by the General Electric metallic arc welder operating over a revolving clamp. All shop welding is automatically done and the field joints made by hand acetylene-gas welding.

**H. J. Lawson:** We have had considerable experience on the Salt River project with welding on repairs of the electrical machinery and other machinery used in the maintenance of the power system and the irrigation system. Especially we have had considerable experience in repairing runners and water wheels on which there was pitting and erosion. Bronze runners are very easily repaired in that manner.

We took one runner out of a 7500-hp. wheel. It was pitted only slightly but we took it out because one vane in the runner was thin. It must have come from the factory that way originally. It has been in operation about 14 years before there was any necessity of thickening the vane. We took out the wheel and built up that particular vane from less than $\frac{1}{4}$ in. thick to $\frac{3}{8}$ in. and made a successful job of it. While doing that we filled up the pitted places on the back side of the vanes. We also built up by welding, the outside periphery of the wheel where the water wear had taken place, and turned it down to proper size. It was then carefully balanced, after which it was practically as good as a new runner.

In repairs of heavy equipment, excavating machines, etc., where there is excessive wear on steel pins and bearings, especially pins that are quite heavy and expensive, we found that welding saves money and gets the job done quickly.

We also have had considerable experience in welding the shafts of turbines where they have cut and grooved within the stuffing boxes. In every case where we repaired them in that manner we have had no further trouble from the part that was welded. The welding has all been done by electric arc.

**C. M. Day:** The particular problem of the Bureau of Reclamation relates to cavitation in cast-iron pipes through which water is discharged under high heads, and at high velocities, from reservoirs. At Arrowrock Dam, on the Boise Project, Idaho, we have 20 58-in. balanced valves mounted on the upstream face of the dam, with 54-in. cast-iron pipes embedded in the concrete dam, and the discharge from each valve may be 800 cu. ft. per sec., resulting in a velocity of 50 ft. per sec.

The jet of water, immediately below the valve, is smaller than the pipe, but as the pipe is completely filled within a short distance, and the water velocity is high, a vacuum exists in the unfilled space, which seems to induce a chemical action, perhaps oxidation, which destroys the metal in the cast-iron conduit. This cannot be erosion as the water is not in contact with the metal. These valves and conduits have been installed about 13 years, and at the top and bottom of the pipes, where the shell is 2 in. thick, the metal has almost disappeared in places.

Our problem is to restore the pipes to practically their original condition. We have tried cement grout and lead, but it will not last throughout one season, and arc welding seems to be the only solution. It seems impractical to remove all of the existing metal throughout the affected area by chipping it out, but it is expected to chisel out at least enough to leave perhaps 50 per cent of the area with clean metal. It is expected that each conduit will require at least 400 lb. of new metal, half of which must be deposited overhead.

It has been suggested that copper or bronze, which resists cavitation much better than steel, be used, but to date we have not found anyone who can successfully deposit these metals in a proper manner.

In a similar valve installation at Pathfinder Dam, where the conduits below the valves were lined with ⅜-in. steel plates, with the rivets countersunk on the inside, any rivet head that projected even 1/16-in. caused this cavitation along the surface of the pipe for at least 8-in. below the rivet, where the vacuum would be caused by the exceedingly high velocity of the water, and in this area the pipe shell would be gradually eaten through This action was so rapid and serious that after two or three seasons' use it was necessary to remove the plate-steel linings, and line the conduits with rich concrete grout, with 24 1.5-in. air-vent pipes embedded in the concrete lining, extending to the point where cavitation existed, to break the vacuum. This method seems to have solved the problem at Pathfinder Dam.

At Arrowrock Dam I am confronted with a large repair problem, and will be very grateful for any suggestions as to how to overcome the trouble and replace the lost metal with new metal that will make a satisfactory bond.

**J. D. Wright:** I should like to inquire why Mr. Day feels that this is a chemical action in what he describes as a vacuum. It would seem to me as though it would be an erosive action at the place where the water enters the cast-iron pipe. I don't see how it can be a chemical action in the vacuum.

**C. M. Day:** I have never seen a complete explanation. In the first place, where cavitation exists the water is at no time in contact with the metal, and for this reason it has always been assumed that the action must be chemical. Because of the conditions of installation it has been impossible to get close enough to make an investigation.

**H. J. Lawson:** At the Roosevelt Dam we have had the same trouble, that is, the pitting of the water wheels. It is commonly known that in a partial vacuum oxidation occurs very rapidly and that this action is simply an oxidation or very rapid rusting.

**J. H. McCabe:** Has there been any development in electric welding of airplane fuselage where they use drawn-steel tubing about 18 or 20 gage? A plant in Colorado Springs is using that type of construction and we have never been able to convince them that the electric arc welding may be used satisfactorily. They employ gas welding.

**J. D. Wright:** I understand that there is a concern on the West Coast, the Boehing Air Transport Company, which is using the metallic welding process in the manufacture of airplane fuselage.

Ordinarily a thin-gage metal is difficult to weld if it is not properly backed up but a skillful operator, with low welding currents, might be able to do it. Whether or not the Boehing Company does it I can't say.

On that gage the current might be from 25 amperes to 75 amperes.

**J. C. Lincoln:** I might give a little experience that was recited to me by Mr. Imlay of the Niagara Falls Power Company. He said that in their plant they had a situation where the pipe was pitting and a hole developed inside the pipe. They drilled the hole out and inserted a lead plug. Subsequently the steel has been eroded all around the lead plug though the plug has not been worn away.

This seems to demonstrate quite completely that this is chemical and not mechanical action. You would expect a lead plug to be eroded much more rapidly than steel pipe under mechanical action.

# Utilization of Lodgepole Pine Timber for Poles

BY R. W. LINDSAY[1]
Associate, A. I. E. E.

***Synopsis.**—With an ever increasing demand for poles used in the construction of power and communication lines, new sources of supply must be developed from time to time. Along the Rocky Mountain Range are found large stands of various species of timber suitable for the production of poles and so far not utilized to any appreciable extent. This paper outlines briefly the selection of lodgepole pine timber for this purpose, relates the past experience with such poles used in certain test lines, and describes in general the production and preservative treatment of the poles.*

* * * * *

## INTRODUCTION

DURING recent years the demand for poles to be used in constructing telephone, telegraph, signal, light, and power lines has increased rapidly. In the eastern part of the United States the cedar stands of Maine have been largely depleted of timber of sufficient size to produce long and large sized poles, and the northern white cedar stands of the Great Lakes region are facing the same situation. Although the blight of the chestnut timber in the Appalachian region has somewhat stimulated the current production of chestnut poles, a large curtailment of the future supply of these poles is inevitable. In all pole producing areas, including the enormous stands of red cedar timber throughout the western coast regions and in the southern pine stands of the South, the hauls are becoming longer, and the charges for stumpage are likely to increase from time to time.

In the face of these conditions, and looking into the future, it has been felt that sooner or later it would be necessary to develop a satisfactory substitute for wooden poles or that new sources of supply must be found. To date, substitutes for wooden poles have not been found to be altogether satisfactory or economical, and it is therefore logical for companies serving the public in sparsely settled territory, necessitating heavy expenditures for pole plant, to look for new sources of pole supply, not only for present consumption but to protect their growing demands of the future.

It has been known for a long time that the Rocky Mountain Range, from New Mexico in the South to Montana in the North, is covered with timber of the proper size to make poles, the principal species available being lodgepole pine, Engelmann spruce, western yellow pine, and Douglas fir. There are various reasons why this timber has not thus far produced many poles, but the chief reason is probably the fact that when these species, with the exception of Douglas fir, are placed in the ground they do not resist the attack of fungi to any great extent. Therefore, it has been recognized that unless a satisfactory treatment could be developed to protect the wood from the infection of fungi, the vast amount of pole timber close at hand could not be economically utilized.

In 1923 an investigation was undertaken by the Mountain States Telephone and Telegraph Company to determine (1) whether or not satisfactory poles could be obtained from the native timber, and (2) whether or not a reliable preservative method could be developed to protect the poles after being placed in the ground. In order to decide whether or not satisfactory poles could be obtained from the native timber, three major questions had to be definitely determined:

a. Whether or not suitable pole-making timber could be found in large quantities in accessible places and close to the railroad.

b. Whether or not, from the standpoints of strength, shape, grain, etc., the timber would be satisfactory.

c. Whether or not poles from this timber could be produced at prices equal to or lower than current prices of other poles.

## AVAILABLE POLE TIMBER

Recent surveys made by the United States Forest Service show the following approximate number of poles that could be produced per acre on certain test sections in several of the national forests of Colorado and Wyoming:

| | |
|---|---|
| Arapahoe Forest | 137 per acre |
| Gunnison Forest | 62 per acre |
| Cochetopa Forest | 47 per acre |
| Leadville Forest | 68 per acre |
| White River Forest | 53 per acre |
| Medicine Bow Forest | 176 per acre |

From sections that have been cut for the purpose of securing ties, sawlogs, props, and poles, and in other sections where special surveys have been made, it has been possible to gain a general idea of the proportion of available poles to the total number of sawlogs and ties that this timber affords. The amount of sawlog and tie timber available in the Colorado and Wyoming National Forests (Wyoming and Teton National Forests in Wyoming not included) is as follows:

| Species | No. of Feet-Board Measure |
|---|---|
| Lodgepole pine | 10,599,078,000 |
| Engelmann spruce | 15,236,420,000 |
| Western yellow pine | 2,031,688,000 |
| Douglas fir | 1,959,289,000 |

From the above information, and allowing fully for

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

trees that would not make satisfactory poles, it can be conservatively estimated that there are now in the Colorado and Wyoming National Forests 200,000,000 trees that would make specification poles. These poles range from 20 ft. to 85 ft. in length with the majority under 50 ft. in length. Besides this growth there is an enormous amount of privately owned pole-sized timber here and there along the range. The States of Montana and Idaho also have very large stands of available pole timber on United States national forests. In Colorado, Wyoming, Montana, and Idaho, this timber, consisting mostly of lodgepole pine and Engelmann spruce, can be secured in large quantities within two to ten miles of existing railroad shipping points which are connected with transcontinental railroads, thus making possible comparatively short hauls.

FIG. 1—LODGEPOLE PINE STAND, LEADVILLE NATIONAL FOREST, COLORADO

The timber controlled by the United States Forest Service will always be productive of poles in very large quantities. The cutting is so programmed that the mature timber is cut first, the less mature next, and so on until the crop is either materially thinned or entirely cut. The age of the present mature stands varies from 75 to 300 years. Lodgepole pine reseeds itself, and after being cut a new growth appears in a short time. Reproduction or second growth in pole sizes can be obtained within 75 to 100 years, depending upon the soil characteristics, growing conditions, etc.

These forests contain a large amount of Douglas fir or red spruce timber, and, because of its fungi resistant properties, this variety of timber has been used in the past for railroad ties, mine props, and poles, and found to be very satisfactory. At the present time, however, the stands are located in more or less inaccessible sections and the growth is often scattered. In view of these facts, Douglas fir poles would now cost more than poles cut from either lodgepole pine or Engelmann spruce.

### TIMBER CHARACTERISTICS AND TESTS

In selecting pole material, the fiber strength in bending is a very important consideration. The strength of pole timber is usually determined by testing the poles in a device by means of which the load, distances from the load to the supports, and the deflections can be accurately measured; and practically all tests of lodgepole pine timber have been made in a standard laboratory testing machine.

Comparative tests[2] of lodgepole pine, Engelmann spruce, and cedar poles were made in 1911 at the University of Colorado, Boulder, Colorado, by Norman Betts and A. L. Heim, engineers in forest products. Twenty western red cedar poles, which were cut near Edgemore, Idaho, and purchased on the Denver market; 22 lodgepole pine poles, cut in the Deerlodge National Forest, Montana; besides 20 lodgepole pine poles and 20 Engelmann spruce poles, fire-killed ten years and cut in Colorado, were all shipped to the University of Colorado for these tests. The strength in bending was determined by placing the poles in a Riehle testing machine and applying a load until failure occurred, and the fiber stress at elastic limit, modulus of rupture, stiffness factor, and modulus of elastic resilience were determined for all poles considered. In addition, the moisture content, annual rings per inch, proportion of heartwood and sapwood, and the weight per cubic foot were determined. The general results of these tests were as follows:

1. Air-seasoned lodgepole pine is superior to western red cedar in all the mechanical properties determined.
2. Fire-killed lodgepole pine is only 80 per cent as strong as western red cedar at maximum load.
3. Fire-killed Engelmann spruce poles are inferior to cedar and pine in all mechanical properties.

The comparative average strength of the cedar, air-seasoned and fire-killed lodgepole pine, and the fire-killed Engelmann spruce is shown clearly in the following table:

| | Moisture Content | Pounds/Sq. In. Modulus of Rupture | Pounds/Sq. In. Fiber Stress at Elastic Limit |
|---|---|---|---|
| Western red cedar | 15.1 | 6,885 | 4,430 |
| Lodgepole pine (air-seasoned) | 21.9 | 7,680 | 5,280 |
| Lodgepole pine (fire-killed) | 16.9 | 5,481 | 4,327 |
| Engelmann spruce (fire-killed) | 16.3 | 4,378 | 3,489 |

In 1926 the Mountain States Telephone and Telegraph Company made similar tests of 53 lodgepole pine poles. All the poles were cut green in the Sargents, Pitkin, and La Veta Pass districts of Colorado. Thirty-one of the poles tested were open tank-treated with creosote, the temperature of the hot bath during the creosote treatment having ranged between 200 deg. and 260 deg. fahr. These poles were shipped to the University of Colorado, at Boulder, and there tested in the same Riehle machine that was used by Betts and Heim in 1911. To determine the modulus of rupture, the poles were placed in the machine in 20-ft. lengths in order to allow both ends of the pole to rest on the bed of the machine. The load was applied at a uniform speed of approximately one in. per min. The deflection of the pole was noted at intervals of 1000 lb. until a total load of 6000 lb. was reached, after which the machine was kept in balance, the deflection being noted at 250 lb. intervals until failure occurred. The characteristics of each fracture were carefully examined, and data were tabulated regarding the relative location of large knots, the type of fracture and whether or not the pole failed in tension or compression. In the tests the annual rings per inch, twist in grain per 20 ft., taper, moisture content, and specific gravity were also determined.

---

[2] This report is covered in detail by *Bulletin No. 67*, U. S. Dept. of Agriculture, dated March 17, 1914.

FIG. 2—RIEHLE TESTING MACHINE AT UNIVERSITY OF COLORADO

The main conclusions drawn from these tests were as follows:

1. The open tank treatment of the poles did not show a positive tendency either for increasing or decreasing the strength of the pole.
2. A slight tendency toward an increase of strength with a decrease in moisture content was noted.
3. Large knots or rings of knots were found very objectionable from the standpoint of strength.
4. The modulus of rupture for the 53 pieces averaged 7723 lb. per sq. in. The average moisture content was 15.98 per cent.

Among those who witnessed these tests were Messrs. H. N. Biggle and S. E. Horton of the Western Union Telegraph Company, Professors H. J. Gilkey and Clarence L. Eckel of the University of Colorado, and Professor W. C. Huntington of the University of Illinois. In this work the University of Colorado heartily cooperated with and assisted the telephone company representatives, as well as providing the mechanical laboratory and the necessary space in the chemical laboratory for the tests.

In 1927 the Bell Telephone Laboratories made tests of pressure-treated creosoted lodgepole pine poles at the University of Colorado. The average modulus of rupture determined in these tests was 6214 lb. per sq. in.

When considered as to shape, grain, and other physical characteristics necessary for satisfactory pole material, all species,—that is, Engelmann spruce, lodgepole pine, Douglas fir, and western yellow pine, would qualify and would rank in the order named in so far as desirability is concerned. This rating is determined by an examination of the timber after it is cut into poles, noting the taper, the size of knots, the twist in grain, the thickness of sapwood, the extent of undesirable scars, and other features inherent in its growth. Western yellow pine grows generally in rather open areas, is found in large trees and has large knots; moreover, extensive pole producing areas are scarce.

### PRODUCTION COSTS

At the time this investigation was made, all cost figures as to stumpage, cutting, skidding, hauling, and loading poles on the cars indicated that poles in most of the available Rocky Mountain areas could be produced at equal or less cost than those shipped in from other sources of pole supply, with the possible exception of southern yellow pine in some districts.

In connection with the cost of producing poles in this territory, the freight factor is very important. For example, poles can be delivered in Colorado from the pole producing areas of either Colorado or Wyoming at a freight rate less than one-half the rate from other sources.

### LODGEPOLE PINE AND EXPERIMENTAL LINES

The lodgepole pine, because of its existence in such large quantities and in such favorable locations from a cutting and shipping standpoint, and also due to its greater fiber strength than that of the Engelmann spruce, was chosen as a logical pole timber with which to experiment.

It was recognized that the successful and profitable utilization of lodgepole pine timber for poles could not be expected unless a satisfactory treatment could be employed that would be effective in protecting the wood from rotting after the poles were placed in the ground; and it is now an established fact that this timber can be so protected, as shown by experience with the following lines.

In 1909 at Norrie, Colorado, 1022 fire-killed lodgepole pine poles were butt-treated with creosote oil. The treatment consisted in placing them in a vat containing the oil, which was heated for a sufficient time, allowed to cool and then drawn off. In this process a penetration of from one-eighth inch to one-fourth inch was obtained, which under present day methods is considered shallow penetration. One very important factor which favored these poles was that they were fire-killed and thus perfectly seasoned, and therefore checked very little after they were placed in the lines. Of these poles 561 were placed in service in Rifle, Colorado, by the Rifle Heat and Power Company, and a line was also built extending from Rifle to their power plant, a distance of approximately 12 mi. These poles were inspected in 1917, 1920, and again in 1926. After 17 years' service, 88.4 per cent of the poles were found to be sound, 2.6 per cent contained decay, and 9 per cent had been removed. All tops were inspected and only one pole showed signs of decay above the ground.

In 1910 the Mountain States Telephone and Telegraph Company placed in service 759 poles which were fire-killed and treated at Norrie in the same manner as the poles placed at Rifle. They were used in a line between Hotchkill and Crawford, Colorado, and to this date, after 18 years' service, no replacements have been made, although 42 poles have been reset and 10 have been reinforced.

Studies of pole line inspection reports show that very few poles in the Rocky Mountain territory become infected and rot above the ground line. This is probably due to the lack of moisture necessary to fungi growth. For this reason it is felt that in this territory it is neither necessary nor economical to treat poles above the ground line.

In the light of this past experience, it is reasonably certain that, when seasoned and properly butt-treated with dead oil of coal tar, lodgepole pine poles will prove both satisfactory and economical for the construction of power and communication lines throughout large areas of the West.

## PRODUCTION

Tentative specifications for lodgepole pine poles were drafted in 1924. In general, these specifications followed those for southern yellow pine poles, taking into consideration, however, the characteristics of the lodgepole pine timber. In November, 1926, specifications for lodgepole pine poles and the creosote treatment thereof were drafted by engineers of the American Telephone and Telegraph Company. These specifications were based upon the experience gained in handling, inspecting, and treating these poles and the tests made to determine their strength in bending. These specifications are still in force.

In 1924 arrangements were made with a timber company to cut approximately 10,000 lodgepole pine poles in the vicinity of Sargents and Pitkin, Colorado. Due to the fact that any oil treatment is of little value in this territory unless the poles are properly seasoned, an effort was made to cut these poles so that they would season during the months of June, July, and August previous to their shipment to the treating plant the following January and February. In the seasoning process the moisture content reduces from 60 to 90 per cent to 20 to 25 per cent. The moisture content is determined by removing a core from the pole, drying it in an oven, and calculating the ratio of the loss of moisture to the dry wood. The seasoning is valuable for three reasons:

1. It reduces the weight of the pole, thereby effecting savings in freight and hauling charges.
2. The shrinkage in the wood fiber produces checks which can be stapled and controlled before the pole is treated and placed in service.
3. Poles having a heavy twist tend to straighten out when seasoning. If poles are placed in the line when green, the gains become out of line as the poles season, which, in some cases, necessitates regaining and retying the wires in order to relieve the tension on one side of the arm.

In an endeavor to control the checking of the poles after they have been treated, anti-splitting staples are used for controlling large season checks. These staples are driven into the poles, spanning the checks to prevent further opening. This practise is also employed to control checks in western cedar poles. During the seasoning process small poles shrink from ¾ in. to 1 in. in circumference, while large poles shrink from 1½ in. to 2½ in. in circumference, depending upon the size of the pole, the age of the tree, and other factors. It is therefore absolutely necessary that poles be cut from six to nine months in advance of using them, in order that they may be properly seasoned. It is also more economical for the producer to cut poles when the sap is up and the bark can be removed easily, which period is generally between the fifteenth of April and the first of August. All cutting operations, of course, cannot be done during this time, but it is a great aid to the cutter if he can cut and peel a large number of his poles at this opportune time.

In most cutting areas it is more economical to haul the poles from the woods to the railroad on snow with sleds than any other way, although in a few localities, where road conditions permit, probably a wagon or tractor could be operated satisfactorily, but in general such a method is expensive. After being cut, limbed, and peeled, the poles must be skidded to the roads, sorted fairly well according to size and class, and placed on timbers to minimize the chance of becoming infected with fungi growth and to aid in their further seasoning. The weather conditions vary along the range from year to year, and it is generally difficult to haul poles before the first of December following the cutting operation. After snow falls in large enough quantities to permit sledding, the poles are hauled to the railroad and there placed on skids, assorted by classes and lengths to await inspection.

It can readily be seen that it is necessary to program carefully the pole requirements far enough in advance to allow the producer to cut and haul the poles at the most economical time and still have the proper time for seasoning.

Returning to the activities of the Mountain States Telephone and Telegraph Company directed toward determining the feasibility of lodgepole pine pole production, and referring to the arrangements made in 1924 for the cutting at Sargents, Colorado, after these poles were fairly well seasoned in the woods or at landing yards along the railroad, they were shipped to Salida, Colorado, for treatment.

### PRESERVATIVE TREATMENT

In the meantime an open tank creosoting plant was constructed at Salida, Colorado, for the purpose of treating poles. Salida was selected as the logical location for this plant, due to the fact that it is near the center of the pole producing timber on the Denver and Rio Grande Western Railroad, and a junction point of the narrow and standard gage routes of this system. The vats of this plant were constructed in general according to plans furnished by the American Telephone and Telegraph Company. There are two treating vats 9 ft. wide, 24 ft. long, and 10 ft. deep. In the bottom of each vat is a steam coil protected by a steel grid. There are two storage tanks for the dead oil of coal tar, one called the cold tank and the other called the hot tank, each containing a heating unit to maintain the oil at the proper temperature. The heating unit in the cold tank maintains the temperature of the oil at approximately 100 deg. fahr. in winter weather and by circulating cold water through this unit during the summer time, the cold oil can be kept at a temperature of approximately 100 deg. fahr. The vats and tanks are supplied with steam from a 40-hp. boiler and under a pressure of 45 lb. per sq. in. A pit is located between the treating vats, in which is mounted a centrifugal pump driven by an electric motor; and the vats, pump, and tanks are connected with eight-inch pipe lines. This arrangement provides for pumping the oil rapidly out of the vat after the hot treatment and pumping cold oil back into the vat to continue with the cold treatment.

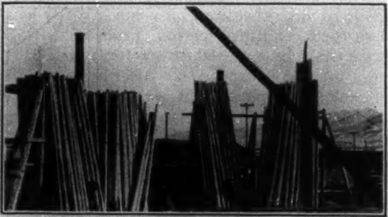

FIG. 3—LODGEPOLE PINE POLES IN TREATING VATS, SALIDA, COLORADO

Experiments supervised by the Department of Development and Research of the American Telephone and Telegraph Company were carried out to determine the proper preparation of the poles and the character of the treatment which would produce the best results. In order to insure even and deep penetration, it was found necessary to remove all pink bark on winter cut poles and also the transparent skin on summer peeled poles. The necessary shaving of the poles was done with an ordinary draw knife. It was also found that the most desirable results could be obtained by treating the poles in a hot oil bath for seven hours at a temperature of from 225 to 250 deg. fahr., after which the hot oil was replaced quickly with cold oil and the treatment continued for an additional seven hours at a temperature of from 100 to 110 deg. fahr. With this treatment a penetration of oil was secured ranging from ⅝ in. to 2½ in. with an absorption averaging 2.2 gal. per pole. It was found that by raising the temperature of the hot bath from 225 to 250 deg. fahr. the absorption of oil greatly increased. Tests were made to determine whether or not this heat affected the strength of the pole, and it was found that it did not materially do so.

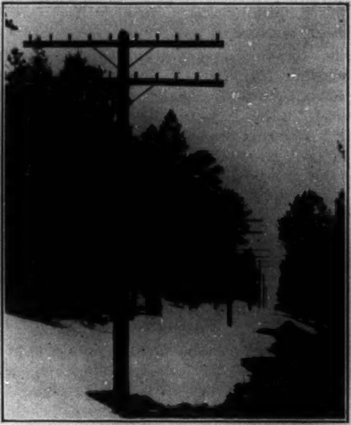

FIG. 4—LODGEPOLE PINE POLE LEAD NEAR DENVER, COLORADO

Test pieces of Douglas fir were treated, and it was found that very little penetration could be secured. Lodgepole pine generally has a thick sapwood while that of Douglas fir is relatively thin. In either species under ideal conditions the sapwood can be penetrated, but very little, if any, penetration can be secured into the heartwood. Tests of fire-killed lodgepole pine timber were made, and it was found that a penetration of more than one-half inch was impossible, regardless of the temperature of the hot bath. In this connection it was impossible to locate stands of suitable fire-killed lodgepole pine in Colorado.

During 1925 approximately 3500 poles were shipped to Salida, where they were prepared for treatment, treated, and reshipped to their destination. The following year 21,000 poles were cut in the vicinity of Sargents, Pitkin, and La Veta Pass, Colorado, treated at Salida and placed in lines in Colorado, Wyoming, and

Utah. In 1927, 16,000 poles were produced in the same locality. In 1927 arrangements were made to expand the production, and contracts were made with a producer on the Moffat Railroad near Phippsburg, Colorado, and one on a branch railroad near Laramie, Wyoming, with the result that the total production in 1928 will be in the neighborhood of 35,000 poles. As the production and consumption of these poles increases, producers should be secured in Montana and Idaho.

## CONCLUSION

There is every reason to believe that tank treated lodgepole pine poles will have an average life in service of at least 15 to 20 years, and possibly longer. There are many factors that affect the ultimate wire load of a telephone pole line, and often this load increases faster than was originally anticipated, with the result that the pole is found to be undersized long before it has been condemned; also, at times other unforeseen factors necessitate moving the pole before its life has been spent. In this territory it now appears that a pole with the lowest possible first cost and a fairly long life is more economical than a pole with a higher first cost and longer life. In other parts of the United States where the density of poles is greater and poles can readily be recovered and reset without damaging the treated portion, different conclusions may be reached.

From the foregoing outline of the investigations thus far made to determine the field of usefulness offered by lodgepole pine timber as a source of pole supply, there can be found justification for continuing and expanding this production, with full confidence that through the employment of proper methods of cutting, seasoning, and treating, lodgepole pine poles will prove highly satisfactory for the construction of the ever increasing number of power and communication lines traversing the western plains and Rocky Mountain region.

# Carrier Systems on Long Distance Telephone Lines

BY H. A. AFFEL[*], Member, A. I. E. E., C. S. DEMAREST[*], Member, A. I. E. E., and C. W. GREEN[†], Member, A. I. E. E.

***Synopsis.**—A previous Institute paper in 1921 gave a very complete résumé of the activities of the Bell System at that time in the development of multiplex telephone and telegraph systems using carrier-current methods. A new type of carrier telegraph system was subsequently described in an Institute paper. In the present paper the authors describe developments which have resulted in improvements in the carrier telephone art since that time. A new, so-called type "C" system is described in detail, together with suitable repeaters and pilot channel apparatus for insuring the stability of operation: the line problems are considered and typical installations pictured. The growth of the application of carrier telephone systems and their increasingly important part in providing long distance telephone service on open-wire lines are shown.*

* * * * *

---

## INTRODUCTION

At the Midwinter Convention of the Institute in 1921, Messrs. Colpitts and Blackwell presented a paper entitled *Carrier Current Telephony and Telegraphy*, TRANS. A. I. E. E., Vol. XL, 1921, p. 205. This described the development work of the Bell System which had resulted in the production of commercial types of multiplex telephone and telegraph systems using carrier-current methods. The paper also gave a brief historical summary and included a theoretical discussion of the methods involved, as well as detailed descriptions of apparatus which had found employment in the telephone plant.

The carrier-current art had at that time emerged from the laboratory to play its part in meeting the practical requirements of telephone service in the field. This step was made possible largely by two tools, now indispensable to the communication engineer, the thermionic tube and the wave filter.

In an ordinary telephone circuit, each frequency component in the voice of the speaker is transmitted by an electrical current of the same frequency. In most cases the electrical equipment of the circuit is not called upon to transmit frequencies above about 3000 cycles per sec. In carrier-current operation, however, the voice-frequency currents are caused to modulate a high-frequency current which thus serves as a "carrier" for the message. In this way an additional telephone channel is obtained, using frequencies entirely above those transmitted in connection with the ordinary voice-frequency channel. By using other high frequencies, several additional messages may be transmitted simultaneously on the same pair of wires. Each channel occupies a certain range of high frequencies. For example, the words of one speaker may be conveyed by a channel employing frequencies from about 23,500 to about 26,000 cycles per sec. At the receiving terminal the various incoming ranges of high-frequency currents are separated by electrical filters. Then by demodulation the original voice-frequency currents are produced again and are transmitted over voice-frequency circuits, the transmission over each channel thus reaching the proper listener. In this way a telephone line already carrying d-c. telegraph and voice-frequency telephone services may be multiplexed so as to provide additional telephone facilities. In a somewhat similar manner the high-frequency range may be used instead to transmit telegraph messages. In the present paper, carrier telephony alone is considered.

The Colpitts-Blackwell paper described two carrier telephone systems which had been developed up to that time, a four-channel "carrier suppressed" system (type *A*), and a three-channel "carrier transmitted" system (type *B*). The initial installation of these systems was made about 1918 on the long lines of the Bell System.

These earlier systems were effective in bringing about economies by avoiding the stringing of additional wire on many long pole lines, but there remained many opportunities for further improvement in performance and simplification of equipment. New problems arose to be solved in connection with the desire to operate the largest possible number of systems on the same pole line. The result has been the development of a substantially improved technique and a new system (the type *C*) which not only has provided much improved performance over its predecessors but which has led to further economies because of reduced costs.

*Carrier Telephone Growth in Bell System.* Whereas the use of the early types of systems was justified in competition with the alternative of additional wire stringing only for distances exceeding 250 to 300 mi., the new system proves economical for distances considerably less. This fact has naturally stimulated the application of carrier telephony in the Bell System. This is shown by Fig. 1, which indicates the growth of these systems in terms of channel mileage afforded by their use. It will be noted that the rate of growth of the systems has increased greatly in the last two or three years, a result of the availability of the improved system.

At the end of 1927 there were in operation about

---

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

130,000 channel miles. By the end of 1928 the figure is expected to be about 230,000. This figure does not, of course, represent a very large proportion of the total toll mileage of the Bell System, which includes many circuits less than 100 mi. in length. It is sufficient, however, to indicate that the carrier telephone systems are a substantial factor in the provision for the growth of the longer haul facilities, where they naturally provide the greatest economies. Their use is, of course, restricted to sections of the country in which open-wire construction is chiefly employed.[1] They have contributed toward lowering the cost of service and in making possible the toll rate reductions which have been put into effect within the past year or so.

*New System Replacing Older Types.* The new type *C* system is essentially a long-haul, multi-channel system. It adds three high grade telephone circuits to the facilities normally afforded by a single pair of wires, and can be used over any distances likely to be encountered in the Bell System. Where repeaters are required they are spaced at intervals of 150 to 300 mi., depending upon particular transmission considerations. Stability of transmission over the several carrier channels is assured, despite the relatively large inherent variations in high-frequency line transmission due to weather changes, by means of a pilot channel.

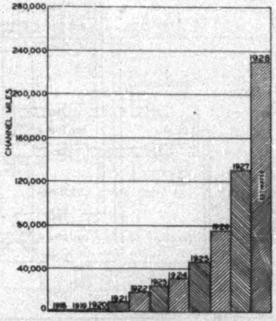

Fig. 1—Growth of Carrier Telephony in Bell System

The service requirements which present themselves in the application of carrier methods are, of course, basically no different from those for commercial talking circuits obtained by other means. The problem is to establish a toll circuit between long distance offices which meets certain standards of transmission, including speech volume, stability, and quality. The latter requires that there must be transmitted a certain band width of frequencies in the voice range. Furthermore, there must exist no appreciable load distortion effects. The circuit must also be relatively free from noise or cross-talk. A signaling system must be provided so that the operators at opposite terminals may call each other. In other respects the system must appear as a normal telephone circuit not distinguishable from an operating standpoint from the other circuits afforded by metallic wire connections. The apparatus installed in the telephone office must conform to certain physical standards of equipment, sturdiness, flexibility, etc. It must be capable of being maintained by trained office forces. Testing facilities must be provided, etc. It is believed that these objectives have been largely realized in the arrangements which are described in this paper.

## THE TYPE *C* SYSTEM

The type *C* system embodies those major technical features which our experience with the older systems has indicated as most desirable. It is a carrier-suppressed, single sideband system, in which respect it is similar to the older type *A* system. However, it has been found possible to dispense with the equal frequency spacing of the channels which was characteristic of the type *A* system, and which involved the transmission of a synchronizing current between two terminals and the harmonic generation of higher frequencies from this synchronizing current. A simplification in apparatus has resulted. This non-harmonic arrangement of channels has further made possible a more efficient use of the frequency spectrum by the fact that the channel bands at lower frequencies can be squeezed together more closely than those of the higher frequencies where the band filters are less efficient due to decreasing ratio of band width to frequency.

The type *C* system requires for each modulator an oscillator as a source of carrier supply. Moreover, since a synchronizing current is not employed at the receiving terminal of the channel an oscillator of the same frequency is required for "demodulation." Advances in the art of designing vacuum tube oscillators of great frequency stability have made it possible to insure that these oscillators, which may be hundreds of miles apart, remain sufficiently close together in frequency so that no noticeable impairment in quality of transmission results.

In the matter of the frequency allocation of the channel bands, the type *C* system possesses one of the essential features of the older type *B* system, that is, the use of different carrier frequencies for transmission in opposite directions. Comparative experience with the type *A* system which, by means of high-frequency line and network balance, employed the same frequency band for the opposite directional paths of the channel led to the conclusion that the systems which avoided the high-frequency balance requirement were more desirable. Also the problem of intermediate repeater amplification is simplified where the opposite directional frequencies are thus separated and grouped. Furthermore, the cross-talk problem between different systems on the same pole line is greatly simplified for reasons which will be discussed later, and a greater total number of channels may usually be obtained on the same pole line.

---

[1] In localities having very heavy traffic requirements such as in the East, extensive use is made of toll cables.

The single sideband transmission employed reduces by about one half the frequency band that would otherwise be required for each channel. The carrier is not transmitted, as the presence in the system of carrier currents of the large magnitude required for a "carrier transmitted" system not only requires greater amplifier load capacity at the repeaters, but may increase the possibility of troublesome cross talk and noise interference. The selectivity requirements of the band filters would also become more severe to keep the carrier of one channel out of the other channels in the system.

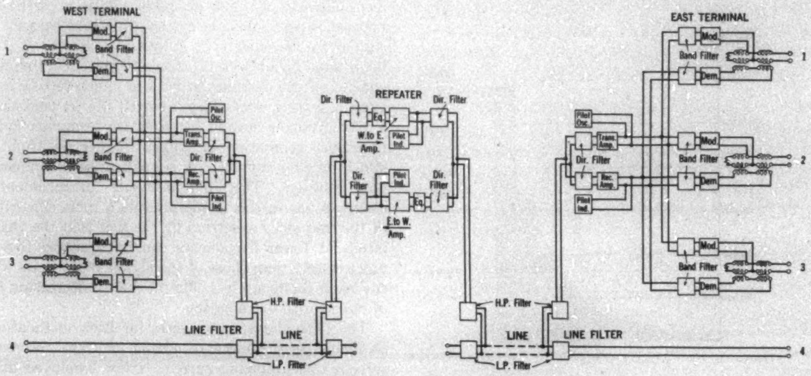

FIG. 2—A COMPLETE CARRIER SYSTEM SCHEMATIC

*A Complete System.* The simplified layout of a complete system is shown in Fig. 2. It will be noted that it includes apparatus at a terminal, a line circuit, a repeater station, a second line circuit, and apparatus at a second terminal. Obviously, the total line length between terminals may be extended by the use of a greater number of repeaters.

At each end there are the terminations of the three carrier channels 1, 2, and 3, and the regular voice circuit 4. These terminations appear, of course, at the long distance switchboard in the same office or in a different office from the carrier terminal. When a subscriber is connected to one of the terminations, for example, No. 1, speech currents pass through the three-winding hybrid coil, thence into the modulator circuit where they are caused to modulate high-frequency carrier current. The resultant modulated bands[2] of frequencies pass through a band filter allowing only the desired band to pass to the transmitting amplifier, thence this band passes through a so-called directional filter and a high-pass filter to the line circuit. The high-pass filter last referred to, in association with its complementary low-pass filter, forms a so-called "line filter" set whereby the regular voice range currents are separated from the higher frequency carrier current at both terminal and repeater offices.

The other two carrier channels function similarly, and the several modulation bands of carrier frequencies join the first channel in passing through the common amplifier and directional filter circuit to the line. At the repeater point the group of bands comprising the three channels passes through the high-pass line filter circuit, thence through a directional filter and line equalizer to the amplifier circuit and outward through the directional and line filter circuit to the next line section. At the farther terminal the combined carrier currents pass through the directional filter and are again amplified in the receiving amplifier. At the output of the amplifier the different carrier channel bands of frequencies are selected one from another by the band filters, thence they pass to the demodulator circuit, are demodulated to their original form and then pass from the output connection of the hybrid coil to their respective terminations.

*Circuit Arrangements at Terminals.* Fig. 3 shows diagrammatically in somewhat greater detail the terminal of the type *C* system. The modulator circuit consists of a two-tube "push-pull" grid-bias vacuum tube circuit in which the carrier frequency is balanced out. A separate oscillator tube circuit of exceptional frequency stability supplies the carrier. The frequency allocation requires the transmission of only the upper or lower sideband frequencies, and the band filter at the output selects the desired band, rejecting the other products of modulation as well as the amplified voice frequencies which are incidentally transmitted through the modulator unit. This sideband current in conjunction with the corresponding currents of the other two sidebands of the outgoing channels passes through the common amplifier. This is a two-stage vacuum tube unit having four tubes in the output circuit arranged in parallel push-pull connection to insure the required load carrying capacity.

---

[2] For a discussion of modulation see E. H. Colpitts and O. B. Blackwell, *Carrier Current Telephony and Telegraphy*, A. I. E. E. TRANS., Vol. XL, 1921, p. 205; R. V. L. Hartley, "Relation of Carrier and Side Bands in Radio Transmission," *Bell System Tech. Jl.*, Vol. 2, April 1923, pp. 90-112.

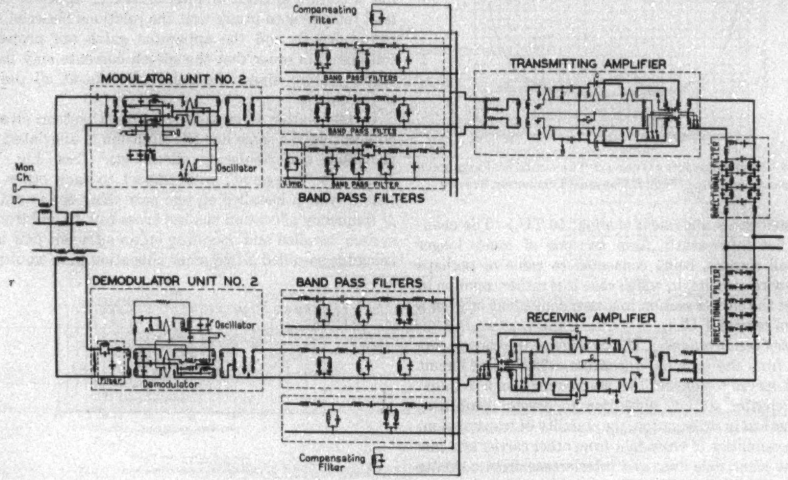

FIG. 3—SCHEMATIC DIAGRAM OF TYPE *C* TERMINAL CIRCUIT

The circuit then leads through a directional filter of either low-pass or high-pass type which distinguishes between the band groups of the opposite directions of transmission as required by the allocation of frequencies. The amplified currents pass through the high-pass filter of the line filter set and thence to the line circuit.

In receiving, the sideband frequencies after separation from the voice currents by the line filter set, pass through the directional filter and an amplifier similar to that used at the transmitting terminal. While the power output required at the receiving amplifier is usually small as compared to that required at the transmitting amplifier, the same unit is used for the two positions to provide flexibility in the adjustments of the receiving gains of the separate channels and for the purpose of economy in production. The different channel currents in the output of the amplifier are selected by the respective receiving band filters and thence pass into the demodulator circuits. In the demodulators the voice frequencies are derived by the modulation of the sideband currents with a carrier frequency supplied by a local oscillator whose frequency is adjusted accurately to agree with that of the corresponding transmitting modulator at the farther terminal. This important problem of synchronization of oscillators is further discussed later in the paper. It is, of course, obvious that if the carrier frequencies of the modulator and the corresponding demodulator of the same channel are not in sufficiently close agreement there will be a serious distortion of the speech currents received over the channel.

The output of the demodulator circuit includes a low-pass filter for suppressing the unwanted components of demodulation, and the circuit thence leads to the channel terminal through the hybrid coil. The function of the latter is to provide a two-wire termination of the channel and it prevents the output currents of the demodulator from reaching in any substantial magnitude the input of the modulator circuit, thus setting up a regenerative action which might result in "singing."

It may be noted that the circuit normally provides for a transmission "gain" or amplification of energy from the switchboard termination to the high-frequency line circuit of approximately 20 TU[3] corresponding to a current or voltage amplification of 10 to 1. In the receiving direction a gain of the same order of magnitude is also available. Of course, the exact amount utilized in a particular case depends on the line attenuation and the desired over-all equivalent of the circuit. It is usually desirable at the transmitting terminal to maintain the level at the maximum possible for the system. The over-all transmission afforded by a carrier system may be noted by the curve on Fig. 4, which shows the relative speech frequency transmission characteristics of a typical channel. Where the carrier channel is employed for terminal-to-terminal business the over-all equivalent at 1000 cycles is ordinarily adjusted to an equivalent of about 10 TU. The channels not infrequently form sections of much longer over-all circuits, being connected to cable or perhaps open-wire circuits, in which case it is rather common to adjust the carrier section to a zero equivalent or even a gain of several T U.

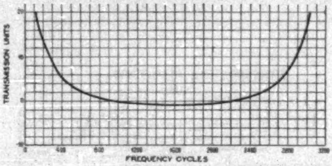

Fig. 4—Representative Over-all Transmission-Frequency Characteristic—Type *C* Carrier Telephone System

*Line Considerations.* The passage of the carrier currents from the terminal apparatus over the line circuit which serves to connect the two terminals, or a terminal and repeater station, gives rise to several problems: the line loss or attenuation, the stability of transmission, the possibilities of cross-talk from other carrier systems on the same pole line, and interference from currents from external sources. These factors must be considered not only in connection with the arrangement of the wires themselves but also in conjunction with the design of the terminal apparatus, repeaters, etc., so that satisfactory over-all speech transmission may result.

As was brought out in the Colpitts-Blackwell paper, the line attenuation at the high frequencies is in accord with the recognized transmission theory. Because of skin effect in the wires and rising losses in the insulators the attenuation increases steadily with frequency. Unfortunately the losses at the insulators are not constant and they increase greatly with the presence of moisture. This brings about an increase in attenuation in rainy weather. Fog, sleet, and wet snow may greatly increase these attenuation changes. There is also a lesser source of variation due to temperature change and its effect on wire resistance.

If care is not taken the carrier currents may be interfered with on the line circuits by cross-talk from other carrier systems and by miscellaneous currents which enter the circuit by induction from the outside. These latter manifest themselves as noise in the carrier channels. This makes it essential to use only the metallic circuit, *i. e.*, two wires well balanced to ground for transmitting the carrier currents. The balance to ground must be maintained at a high degree by frequent transpositions in the wires. Even with these precautions unavoidable residual unbalances may permit a certain amount of interference to appear. The final remedy is to insure that the relations between the circuit length and the apparatus gains are properly considered in order that the speech currents may have ample margin above the noise currents at all points in the circuit.

In the matter of cross-talk between systems closely adjacent on the same line the situation is alleviated by providing two frequency allocations. (See Fig. 5.) These are "staggered" with respect to each other, so that a system installed on one pair using the so-called *N* frequency allocation has less cross-talk to and from a system installed and operating on an adjacent pair and using the so-called *S* frequency allocation than would be the case if both systems employed the same allocation. The maximum upper frequency required is raised only slightly by this arrangement.

*Repeaters.* Repeaters must be employed when the distance exceeds that for which terminal transmitting apparatus is effective in maintaining the transmission level well above the line noise. The function of the repeater is, therefore, to amplify the carrier currents so that they pass on to the succeeding line section at a magnitude comparable to that sent out from the terminals. Obviously, the design of the repeater with respect to its gain and level carrying capacity, etc., presents a wide range of possibilities, depending on the distance of transmission, frequency, etc.

It has been found most practical to install the repeaters along the route at approximately the spacing of the voice-frequency repeaters on the same wires. This means a spacing of from 150 to 300 mi., and occasionally slightly over 300. To have in the same office both voice-frequency and carrier repeaters reduces the equipment, simplifies the maintenance problem, and makes it possible to use the same sources of power supply. The gain and the load carrying capacity are, therefore, determined by this spacing, the gain being controlled by the attenuation loss between the repeaters, and the load carrying capacity by the output level desired because of noise considerations.

The higher attenuation of the line in the carrier range of frequencies means that the carrier repeaters must have a maximum gain of approximately four times that of the voice repeaters operated on the same wires. Whereas gains of the order of 8 to 15 TU may be readily supplied by voice repeaters using balance and so-called "two-wire" operation, the 30 to 45 TU gain required by the carrier repeaters necessitates non-balanced or "four-wire" operation or its equivalent, by using different frequencies in opposite directions and directional filters for the prevention of "singing."

Fig. 6 is a schematic diagram of the circuits comprising a typical repeater station including loading, compositing apparatus, and line filters. After passing through the high-pass line filter the carrier currents arrive at the high and low group directional filters which distinguish between the oppositely directed currents. These filters are substantially the same as those used for similar purposes at the terminal stations.

FIG. 6—GENERAL SCHEMATIC OF CARRIER REPEATER CIRCUIT WITH ASSOCIATED LINE EQUIPMENT

It is, of course, required in the design of the directional filters that in each direction the filters must pass a frequency band sufficient to transmit properly the three carrier channel bands. In addition to this the filters must present a loss outside of the transmission band which is sufficient to prevent the two-way amplifier circuit from "singing." This means that considering the closed loop circuit of the two amplifiers and the four directional filters the attenuation in this loop must be considerably greater than the sum of the gains or amplification of the two amplifiers. There are also other requirements which these filters must meet which are discussed later.

The amplifiers are the same as used for group amplification purposes at the terminals. Each consists of a two-stage reactance-coupled vacuum tube circuit having four tubes in parallel push-pull connection in the output circuit. The carrying capacity of this amplifier with the standard plate voltages is about one watt in the output, and the over-all amplification or gain including incidental filter losses is about 30 TU. Where gains greater than 30 TU are necessary in the higher frequency group provision is made for the addition of an amplifier stage ahead of the unit shown, which adds approximately 15 TU gain. At the same time provision is made for the addition of greater directional filter selectivity.

An important feature of the repeater circuit is the equalizer which is connected ahead of the amplifier. Because the line circuit attenuation varies with frequency and is greatest at the higher frequencies, it is necessary that the amplification introduced at a repeater point be varied with frequency. The amplification introduced by the amplifier unit itself is substantially uniform with frequency. The equalizer network, however, by introducing a loss which is a minimum at the highest frequency of transmission and which increases for the lower frequencies makes the over-all repeater amplification a function of frequency and in general proportional to the line attenuation which it is designed to overcome.

A typical over-all gain characteristic of the repeater is shown in Fig. 7. The adjustment of the exact amount of gain desired at any time is made by the potentiometer at the input of the amplifier.

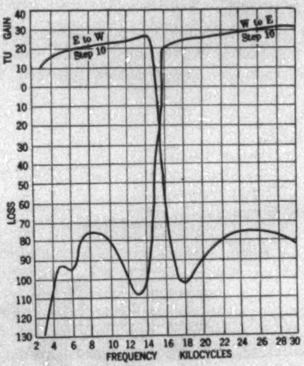

Fig. 7—Over-all Transmission Characteristics of Carrier Telephone Repeater Station

*Pilot Channel.* As noted previously the attenuation of open-wire circuits of substantial length is affected by weather conditions. This makes it necessary to make occasional gain adjustments throughout the system. The extent of these adjustments is determined by means of the pilot channel which provides a visual indication of the transmission levels of the carrier system in both directions of transmission without interfering with the speech currents over the channels themselves. It is, in effect, a separate constant frequency carrier channel allocated between certain speech channels in each transmission group.

The operation of the pilot is relatively simple. At each repeater point and receiving terminal there appears a meter for registering the output level of the amplifier. The pointer of the meter is expected normally to rest on the zero or normal level layout of the system. If a change in the attenuation of the line circuit causes a departure in the transmission level, the meter reading shows a corresponding "up" or "down" indication and by adjustments of the repeater or terminal amplifier potentiometers the level may be returned to normal. An alarm circuit is furthermore provided at the receiving terminal so that when the level has departed by more than a predetermined amount, say ± 1.5 TU, from the desired normal, the operating attendant is called in to make the adjustment.

A high-frequency current of constant amplitude is transmitted from each end, and the meter indications are measurements of this current at the output of repeater amplifiers, and at the receiving terminal amplifiers (see Fig. 2). A separate pilot frequency is utilized for each direction of transmission. Because no communication is carried on over this pilot carrier current, the band provided is extremely narrow, and no appreciable portion of the frequency spectrum is sacrificed.

The frequency selected for the pilot channel must coordinate with the other carrier system frequencies. The two frequency allocations of the type *C* system require different pilot channel frequencies because their speech channels occupy different frequency bands. The apparatus has therefore been made so that the frequency of the pilot current can be adjusted to any value desired in the carrier range. The frequency selected for a given system may be determined by local conditions of cross-talk or interference, although in general the preferable location is between the channel bands as noted in Fig. 5. The amount of current which is used is limited by its interfering effect into adjacent channels or into other carrier systems on the same line, and it is ordinarily of a low value, of the order of 2 to 6 milliamperes on the line.

Fig. 8 shows schematically the principal features of the terminal pilot-channel circuit as a whole. The oscillator at each transmitting terminal which produces the pilot current is connected to the carrier circuit at the input to the transmitting amplifier, in parallel with the band filters. This current is amplified with the speech currents and transmitted through the directional filter to the line. The attenuated pilot and sideband currents pass from the first section of the line into the receiving directional filter of the first repeater and enter the amplifier. The pilot channel indicator circuit is bridged across the output of the amplifier, and is tuned to

Fig. 8—Schematic of Pilot Channel Circuits. (The Alarm Circuit is used with Terminals Only)

discriminate very sharply against all but current of the pilot frequency. This circuit has a high impedance relative to the line, so that only a very small percentage of the pilot current is drawn from the line at a repeater point. The remainder is transmitted through the outgoing directional filter and over the subsequent section of the line.

That portion of the pilot current which enters the indicator circuit is amplified and rectified in the vacuum tube detector, and the output current is read on a d-c. milliammeter. As stated above this meter is calibrated to read in TU above and below a mid-scale position which represents a normal transmission level to which the system is initially adjusted.

Entering the receiving terminal of the carrier system, the pilot and speech currents pass through the directional filter and are amplified. As at the repeater, the pilot indicator circuit is bridged across the output of the amplifier. At this terminal, in addition to showing level, the output of the indicator actuates an alarm circuit which operates when the transmission level at this point varies from normal for a set interval of time by more than a prescribed amount. This delay action in the operation of the alarm provides selectivity against slight interference into the pilot channel from currents on the other channels of the system and thereby insures that the alarm indicates a definite level change.

The pilot channel thus insures that the high frequency portion of the system is continuously checked with the exception of the individual channel band filters and modulator and demodulator units. These, however, are particularly stable in operation and require no unusual attention in maintenance. Of course, the over-all check is made at only the pilot frequency in each direction. Variations of line equivalent caused by weather changes increase in magnitude with frequency. Therefore, corrections must be made in the gain relations of the individual channels whenever these weather changes are great. Fortunately the corrections follow a fairly definite relation with variations of pilot level and are ordinarily made by the terminal attendants on the channel potentiometers controlling the demodulator gain by reference to a table. This table shows the relations between the required gain changes at the three channel frequencies in terms of changes at the pilot frequency.

The type of oscillator is essentially the same as that used in the type *C* carrier systems for producing the carrier frequencies. It is controlled by condensers which include an adjustable air condenser for tuning to the particular frequency desired.

Two indicators are located at the repeater, one for each direction of transmission. Each indicator circuit consists of a vacuum tube rectifier operating from coupled tuned circuits into a d-c. milliammeter having a special scale calibrated in transmission units. The filament and plate currents and bias potentials are obtained from the standard 130-volt battery. The advantage of using the same battery for the several functions is that it makes possible the stabilization of the rectifier output with power variations. An adjustable grid bias voltage is obtained from the negative drop of the filament circuit with an opposing 3-volt dry cell battery connected in series. With this arrangement normal variations in the 130-volt source cause only a negligible change in the indicator meter readings.

At the receiving terminal, in addition to the indicator circuit which is the same as at the repeater, an alarm circuit is provided as noted above. A sensitive marginal relay is connected in series with the indicator meter. When this relay operates, it starts the delay circuit by removing ground from the grid condensers of the alarm tube. The leakage through the grid resistances then causes the condenser potential, which is the grid potential of an auxiliary rectifier tube operating from the same power source, to decrease slowly, resulting eventually in a rise in the current of the plate circuit of the alarm rectifier tube. If the marginal relay remains operated for a given length of time, the alarm tube plate current will rise to a value necessary to operate the alarm relays. For shorter periods of operation the normal highly negative grid potential of the rectifier tube is restored and no alarm is operated. The timing of the delay circuit is adjusted by the values of the grid leak resistances and condensers. A delay of about 15 sec. is usually employed which effectually prevents false operation due to occasional transients such as speech interference. The adjustment of the contacts on the alarm relay is ordinarily such as to cause an alarm to be given at limits of ± 1.5 TU variation.

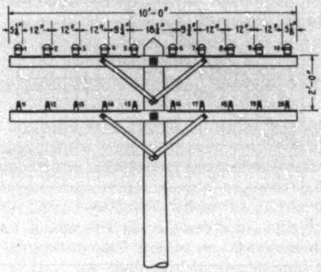

Fig. 9—Showing Arrangement of Wires on Telephone Pole Line

### General Transmission Considerations

*Lines.* The typical open-wire telephone line consists of a number of 10-ft. crossarms spaced two ft. apart on poles whose height varies from 30 ft. upward depending on local conditions. The poles are spaced at an average interval of 130 ft. Each crossarm carries 10 wires. The wires are normally spaced at 12-in. intervals, except in the case of the so-called pole-pairs which straddle the pole and whose wires are about 18 in. apart. (See Fig. 9.) The construction includes pins and glass insulators for supporting the wires.

There are three gages of wire in common use in the telephone plant, having diameters of 104, 128, and 165 mi., respectively. The largest gage, 165-mil pairs naturally afford the lowest attenuation and have been generally used in connection with the application of the longer systems. The pairs of this sized conductor are, however, now fairly well used up for carrier purposes and new installations are being made more often on the smaller diameter circuits.

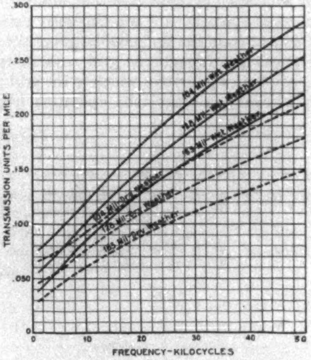

Fig. 10—Attenuation Curves for Open-Wire Lines of Different Gages at High Frequencies

Typical attenuation curves for the three gages of wire and the extremes of weather conditions are given in Fig. 10. It will be noted that the wet weather attenuation may be as much as 40 per cent higher than the dry weather attenuation. These variations are greater at the higher frequencies.

It is interesting in this connection to consider the effect of the possible variation in a practical case. Take, for example, a 165-mil pair 200 mi. long with a carrier channel frequency at 25 kilocycles. This means a total attenuation of 20 T U in dry weather and 29 T U in extremely wet weather, a variation of 9 TU or a current ratio of about 3 to 1. In the case of a still longer line these possible variations present rather startling figures. For example, in a 1000-mi. circuit the variation would be five times the above or 45 TU, which would mean that if the circuit were set up to have a proper volume of transmission in dry weather and rain occurred over the whole line it would cause the speech at the receiving end to drop to but 1/180 of the desired volume if the proper readjustments of gain at the repeaters and terminals were not made. Fortunately, these line variations occur gradually, at least in the case of the longer lines.

In connection with most carrier installations measurements are made[4] of line characteristics prior to the installation of the apparatus. An interesting picture is presented in Fig. 11 which shows the attenuation variations with time on a particular line (about 110 mi. in length) during the period in which a storm arose to cause the attenuation to increase. Later, when the insulators had dried off, the corresponding drop in attenuation is evident. From these variations it is quite obvious that means such as afforded by the pilot channel are needed to insure that the talking circuits provided by the carrier channels remain at substantially constant volume.

In addition to the improvement in stability effected by the use of pilot channel apparatus, substantial advances have been made in the design and application of special types of line insulators in which the high-frequency losses, particularly in wet weather, have been appreciably reduced resulting in still further improvement in stability. The attenuation data given above are for the lines equipped with the older standard types of telephone insulators, which are still employed on the majority of circuits in the telephone plant. However, the newer types of improved insulators are now being applied and their use makes it possible to reduce the wet to dry weather attenuation variation by a factor of about 3 to 1 and to reduce the absolute value of attenuation at the higher frequencies by as much as 25 per cent. Further information describing the development work which has made possible these improved insulators will be made available at a later date.

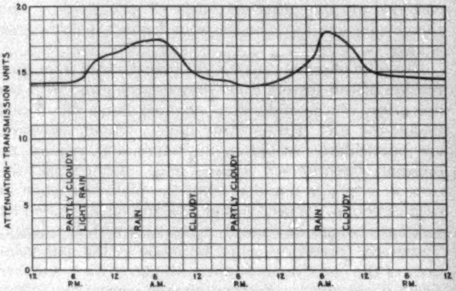

Fig. 11—Variations in Attenuation of a Particular Open-Wire Circuit

While the circuits employed for the transmission of carrier telephone systems as noted above, are largely of open-wire construction, where these circuits pass through the more populated districts of the country it is frequently necessary to insert sections of cable. The smaller closely spaced wires of cables make the problem of attenuation at high frequencies more serious, even where the cables are relatively short, say a mile or so in length. Typical attenuation curves of non-loaded cable pairs are shown in Fig. 12.

---

[4] *High-Frequency Measurements of Communication Lines*, H. A. Affel and J. T. O'Leary, A. I. E. E. Transactions, Vol. XLVI, 1927, p. 504.

This situation has led to the development of a special type of cable loading which permits making a substantial reduction in the attenuation for the higher frequencies and which also makes the characteristic impedance of the cable circuit more closely simulate that of the open-wire circuit so that the reflection effects discussed in detail later are thus greatly reduced. This is important, for, whereas the open-wire circuit characteristic impedance varies from 600 to 700 ohms, the non-loaded cable impedance is of the order of 130 to 150 ohms and the reflection losses and also certain resultant cross-talk effects as discussed later are therefore very substantial for even short lengths of non-loaded cable. The present standard types of carrier cable loading systems[5] provide for the use of loading coils spaced at intervals of approximately 930 ft. When loaded, the cable circuits have a characteristic impedance loosely approximating the open-wire impedance over the frequency range used in carrier transmission. This same carrier loading also greatly improves the characteristics of the voice circuit. The high-frequency attenuation is reduced to approximately one-half the non-loaded condition. A special type of cable loading is also available for use in improving the transmission characteristics of office cable and wiring and very short intermediate and entrance cable.

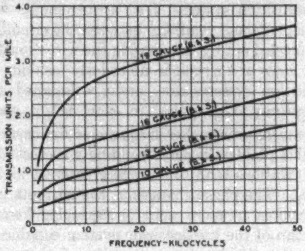

FIG. 12—ATTENUATION OF NON-LOADED CABLE CIRCUITS

*External Interference.* The carrier channels are unusually free from noise due to extraneous induced currents. This, however, is the result of attention to this factor in the design of the apparatus and in laying out the installations rather than anything inherent in the high-frequency feature as such. Our experience has indicated that it is possible, if care is not taken, to have interference from the following external sources:

a. Harmonics of power frequencies.

b. Irregular frequencies produced by abnormal power line actions, such as arcing insulators, charging lightning arresters of certain types, electric railways, series street lighting, etc.

c. Power line carrier systems.

d. Powerful transoceanic radio transmitters.

e. Lightning and other atmospheric disturbances.

In the matter of harmonics of the power line frequencies, the source of their generation normally limits them to very low magnitudes in the high-frequency range which has been employed for carrier systems on telephone lines. In this respect the carrier systems are, in general, affected to a lesser extent than the normal telephone circuits in the voice range. In the latter case, the power circuit harmonics frequently present serious interference problems because the harmonics in the power circuits are substantially greater at the lower frequencies.

Under particular conditions, however, such as, for example, in connection with a series street lighting system operated with individual series transformers or auto-transformers, where a burned out lamp causes the saturation of the transformer magnetic circuit, induced harmonics of considerable magnitude, up to 30,000 cycles and over, have been measured in the carrier telephone circuits. Under the same conditions, however, much larger harmonics are present in the voice-frequency range, so that the induction in the normal telephone circuit is more severe than the carrier circuit.

A much more severe source of carrier interference has been found to result from the abnormal actions of power line circuits in which arcing phenomena occur. Interference of this sort has been noted and traced to such sources as arcing insulators, tree leaks, pantograph and trolley collector sparking, charging lightning arresters, unusual commutator or slip-ring sparking, switching, etc. In the early days of operation of carrier systems, interference of this type formed a not uncommon source of disturbance. The situation was remedied in some cases by cooperation with the power companies concerned. On the whole, this source of interference has been greatly reduced in the past few years.

On occasions the carrier telephone systems have been interfered with by power line carrier systems operating on near-by power lines. Considering the wide-spread use of power line carrier telephone systems and the fact that they normally involve a transmitting power many times that of the systems described in this paper, this would, no doubt, be a more common source of difficulty were it not for the fact that such power systems adjacent to the telephone systems are operated well above the frequency range of the telephone line carrier systems.

---

[5] Thomas Shaw and Wm. Fondiller, "Development and Application of Loading for Telephone Circuits," *Bell System Tech. Jl.*, April 1926, pp. 221-281.

Energy picked up from the high-power transoceanic radio telegraph stations, transmitting at frequencies in the carrier range, is an occasional source of interference, particularly in the East where carrier systems are located relatively close to the radio stations. The open-wire telephone lines act as long-wave antennas and intercept the radio energy. This, of course, enters initially on the longitudinal wire circuit to ground. Due to residual line unbalances, some energy is, however, unavoidably passed on to the metallic circuits on which the carrier systems are operated, and enters the speech channel in the form of a tone or note similar to a heterodyne signal at a radio telegraph receiver.

Lightning and general static disturbances form a substantial part of the background noise which is found on all carrier lines. Its general magnitude is ordinarily small, except under certain conditions such as the case of near-by storms.

*Transmission Levels.* In the design and laying out of type *C* installations, the transmission level of a system is ordinarily not permitted to fall below a certain figure, which under particular circumstances might be about − 25 TU, with respect to the transmitting terminal. A transmission level diagram will serve to explain this limitation.

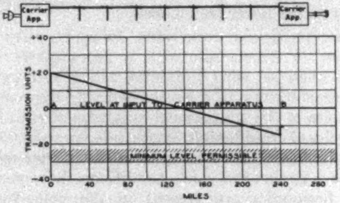

FIG. 13—TRANSMISSION LEVEL DIAGRAM

Let it be assumed that it is desired to effect carrier transmission using a type *C-N* system between points *A* and *B*, 240 mi. apart on 165-mi. conductors. The highest frequency channel is normally considered, which in this case would be 26 kilocycles. The total attenuation of the line at this frequency, as determined from the line attenuation data already presented, would be 35 TU for wet weather conditions of operation. A level diagram would accordingly picture the situation as noted in Fig. 13. At point *A*, sufficient transmitting gain would be provided by the equipment to bring the sending level to + 20 TU. The line attenuation in connection with transmission over the 240-mi. circuit at point *B* would bring the level to − 15 TU. In order to obtain an over-all talking circuit of, say 10 TU, it would be necessary to operate with a receiving gain of 5 TU. It will be noted that in this particular layout the minimum line level is well above the limit set above. In fact, computations would indicate that the line circuit might be extended to the total length of about 300 mi., before the level limits would be exceeded. On longer lines, however, involving many repeater sections, the level limits are raised because of the cumulative effect of noise entering the circuit from a greater number of sources.

The line circuit illustrated is of the simplest type and in a practical case involving sections of intermediate and terminal cable construction, the attenuation would be considerably greater and the effective geographical distance covered for a particular type of apparatus would, therefore, be less.

*Cross-talk.* Telephone circuits which are simultaneously operating in close proximity on a pole line are normally subject to cross-talk because of the mutual inductance and capacity relations between the wires. The problem which this presents in a pole line structure carrying many circuits requires careful consideration, even where the frequencies are no higher than the voice range. The problem is cared for by the application of transposition systems, *i. e.*, arrangements whereby the effect of these relations between the circuits tends to be canceled out by transposing the wires constituting the two sides of a circuit in an orderly fashion. These transposition systems are carefully designed and the transpositions to be applied in each circuit specified.[6]

When using still higher frequencies for carrier purposes, this problem is correspondingly increased as the mutual relations tend to become greater at higher frequencies. The phase changes as the currents progress along the lines are more rapid for the higher frequencies. The design of the transposition system capable of permitting the simultaneous operation of a number of carrier systems on the same pole line is a difficult problem. The subject is one of great complexity and to give it complete consideration would require more space than is available here. It may be noted, however, that, by means of special transposition layouts installed in the circuits being used for carrier transmission, successful operation is being obtained with a large number of carrier systems on the same pole line, both telephone and telegraph. The locations of transpositions in circuits used for carrier transmission occur more frequently than in circuits restricted to operation at voice frequencies, in some cases as frequently as every other pole.

Several factors in the apparatus design have contributed in lessening the degree of hardship imposed by the cross-talk problem:

1. The standardization of arrangements whereby the same frequencies are only employed in a given direction on systems on the same pole line.

---

[6] H. S. Osborne, *The Design of Transpositions for Parallel Power and Telephone Circuits*, A. I. E. E. TRANSACTIONS, Vol. XXXVII, 1918, p. 897.

2. The equalization of the transmission levels between paralleling systems.
3. The use of "staggered" frequency allocations for systems in closest proximity.
4. A careful consideration of impedance relations in the line circuits and apparatus.

*Frequency Directions.* The importance of the use of a separate frequency for each direction of transmission may be considered by reference to Fig. 14. If there are two paralleling telephone circuits employing frequencies $f_1$ in the same range, and if there exists between the two circuits a certain amount of cross-talk, when there is a talker at the terminal of one system (No. 1) and a listener at the same terminal of the other system (No. 2), then the speech from the talker at the high level will enter directly into the sensitive receiving circuit of the listener. This is commonly called "near-end" cross-talk. In the case of a carrier circuit, the transmitting terminal would involve a certain amount of amplification. The receiving circuit would likewise, so that the net effect would be that the cross-talk between the two circuits would be amplified by the combined amount of gain or amplification present in the sending and receiving circuits. In telephone parlance it would be stated that this is a situation in which substantial level differences exist between the two circuits.

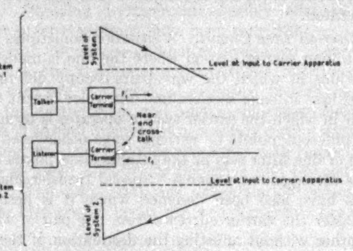

FIG. 14—DIAGRAM ILLUSTRATING OCCURRENCE OF NEAR-END CROSS-TALK BETWEEN CARRIER SYSTEMS EMPLOYING THE SAME FREQUENCY FOR OPPOSITE DIRECTIONS OF TRANSMISSION

On the other hand, in the case of two adjacent carrier systems employing the same frequencies for the same direction of transmission, a cross-talk situation involving only "far-end" cross-talk would exist, as illustrated in Fig. 15. This assumes that near-end cross-talk by reflection as discussed later has been eliminated. In this case the talker and the listener would be situated at opposite terminals of the paralleling circuits and the cross-talk, while being amplified like the near-end cross-talk by the total gain in the transmitting and receiving circuits, suffers the attenuation of the line circuit which more than offsets the amplification. This is, therefore, a very substantial factor in favor of the two-frequency method of operation.

At the carrier frequencies, it has been found impracticable to design transposition arrangements providing for systems where the same frequencies are transmitted in opposite directions. It has been found that, while the two-frequency operation may mean fewer two-way operating channels within the same frequency range on a single pair of wires than would be the case if the same frequency bands were provided for opposite directional transmission, the net result in the former case is to make it possible to obtain a greater number of channels on a pole line having many pairs of wires. The need for the directional coordination of frequencies has led to the general adoption of rules throughout the Bell System whereby the systems are all installed so that the low-frequency directional group of channel transmits east to west or north to south and the high, frequency directional group in the reverse direction, west to east or south to north.

*Level Equalization.* A situation involving an exaggeration of the crosstalk between two paralleling carrier systems may, of course, arise, even in the case of systems involving the transmission of the same frequency in the same direction for the two systems, if the transmission levels of the systems are not the same. If, for example, two systems operating between the same terminals are set up to have the same over-all talking equivalent, and one system has a transmitting gain 10 TU higher than the other, the second system must have 10 TU greater receiving gain in order to provide the same over-all equivalent. This would mean that this system would receive from the first system 10 TU higher crosstalk than if the levels of the two systems were alike. Efforts are therefore made in "lining up" the paralleling systems on a pole line so that as nearly as possible the same level relations are obtained for all systems, and the crosstalk tendencies are thus minimized.

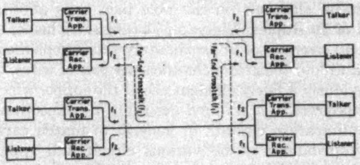

FIG. 15—DIAGRAM ILLUSTRATING OCCURRENCE OF FAR-END CROSS-TALK ONLY IN CARRIER SYSTEMS EMPLOYING DIFFERENT FREQUENCIES FOR OPPOSITE DIRECTIONS OF TRANSMISSION

*Staggering of Frequency Bands.* A substantial reduction of cross-talk is obtained through the staggering of adjacent system frequency allocation as previously noted. Fig. 5 has shown the frequency allocations of the *C–N* and *C–S* systems. Because present standard types of telephone transmitters and receivers have response characteristics which exhibit the greatest sensitivity in the vicinity of 1000 cycles, as the bands of two adjacent channels are shifted from an overlapping position, the cross-talk is appreciably reduced. In this case, also, the overlapping cross-talking points are always opposite sidebands and the intelligibility is completely lost even in the case of a substantial overlapping.

It is customary to install *C–N* and *C–S* systems on the two side circuits of a phantom group. The phantom group comprises four wires which are most closely associated electrically because they are employed not only to provide a telephone circuit on each pair of wires but a phantom telephone circuit each side of which is comprised of one pair of wires in parallel.

A typical arrangement of facilities afforded by one crossarm of the telephone line is illustrated by Fig. 16. It will be noted that this crossarm provides a total of twelve carrier telephone channels, five regular telephone circuits, two and one-half phantom circuits, thus making a total of 19½ telephone circuits. The telegraph facilities would total ten regular grounded d-c. telegraph circuits, one for each wire, and ten carrier telegraph channels on the pole pair, thus affording a total of 20 duplex telegraph channels. This is, therefore, an average of approximately four telephone channels and four telegraph channels per pair of wires, which is obviously a fairly efficient use of the copper wire.

FIG. 16—ARRANGEMENT OF COMMUNICATION FACILITIES ON ONE CROSSARM

*Impedance.* It is found desirable in connection with communication circuits in general to match carefully the impedances of the various circuit and apparatus components if for no other reason than to insure the best transmission by keeping the reflection losses at a minimum. In connection with carrier systems the matter of crosstalk constitutes an additional important reason for doing this. As noted above, the cross-talk situation is simplified by the standardization of frequency arrangements by which only far-end cross-talk is normally received. This not only reduces the level differences at which cross-talk takes place as explained, but it simplifies the transposition design problem because near-end cross-talk is normally greater in magnitude than the far-end cross-talk. However, if the line circuit is irregular, *i. e.*, if there are abrupt impedance differences in the circuit as it passes from point to point, which bring about wave reflections, these may result in near-end cross-talk being reflected and appearing as far-end cross-talk, thus adding to the true far-end cross-talk and making it more difficult to keep within desirable limits. For this reason every effort is made in the layout of the carrier lines to avoid such reflection effects. This makes it desirable to load even relatively short cables including office cables and wiring. The apparatus terminal impedances are also carefully designed so that their values simulate the characteristic impedance of the line circuits over which the systems are operated.

*Over-all Line Circuit.* A situation sometimes occurs in a long carrier system where the line is made up of sections in which the wire pairs occupy different pin positions in each section, and the voice circuit on the pair in which the carrier system operates is terminated at different points or perhaps joins other lines. The use of line filter sets at the intermediate points makes this arrangement possible. Special transfer line filter sets have also been designed where it is desired to transfer the carrier currents from one pair of wires to another without affecting the destination of the voice circuits and with a minimum impedance irregularity for either circuit. These line filters are sometimes mounted on poles so that this transfer may take place where lines join at an outside point and where office equipment cannot be installed. A circuit arrangement illustrating the use of the pole-mounted high-pass transfer filter set is shown in Fig. 17.

## EQUIPMENT PROBLEMS AND TYPICAL INSTALLATIONS

The increasing use of carrier telephony as a substitute for line construction in providing toll facilities on long circuits has, like the development of toll cables, resulted in further increasing the proportion of the plant investment represented by the equipment within the offices. It has likewise required that a greater part of the maintenance effort involved in taking care of a given number of facilities be devoted to the equipment. These factors have made the design and arrangement of the carrier equipment matters of considerable importance. Recent developments in these respects have, therefore, been directed toward obtaining a high degree of adaptability of the carrier equipment to practical use in the telephone plant. Economies in

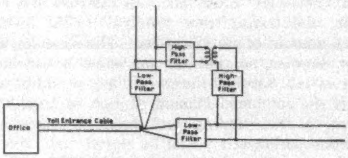

FIG. 17—SCHEMATIC OF HIGH-PASS TRANSFER LINE FILTER CIRCUIT

design have also resulted which have been an important factor in extending the usefulness of the equipment.

The type *C* carrier telephone equipment is mounted on panels employing a uniform dimensional system in a manner similar to the other recent telephone developments. Arrangements have been devised so that in the future this mounting method will permit the desired close association between the carrier filters and other related apparatus in the lines in order to minimize high-frequency losses and impedance unbalances within the offices. Signaling arrangements flexibly adapted to present plant conditions have been provided.

The high frequencies and power levels used in carrier telephony, and the frequency conversion functions of the system are the principal electrical factors which affect the arrangement and amount of equipment involved. The high frequencies necessitate careful wiring, shielding, and location of certain units with respect to others to avoid undesirable inductive and impedance effects. The modulation and demodulation processes and the high energy levels required necessitate the use of numerous vacuum tubes, with the consequent need of suitable sources of power.

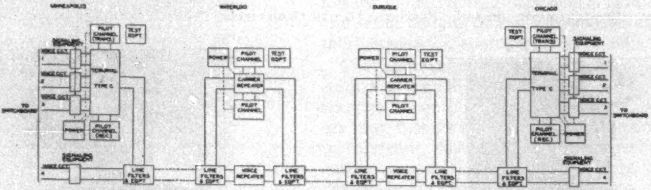

FIG. 18—ELEMENTARY DIAGRAM SHOWING PRINCIPAL EQUIPMENT GROUPS IN TYPICAL TYPE *C* CARRIER TELEPHONE SYSTEM

*Typical System Equipments.* As noted previously, a long carrier telephone system involves equipment at a number of intermediate repeater stations in addition to that at the terminals. Fig. 18 shows the principal equipment groups involved in a typical long carrier system. The particular system illustrated is one of those between Minneapolis and Chicago, with repeater stations at Waterloo and Dubuque, Iowa. The carrier repeater equipment is ordinarily additional to voice-frequency repeater apparatus used in the wire line as mentioned above and is connected so that the high-frequency currents for the carrier pass around the voice-frequency repeater. The wires concerned are employed also for d-c. telegraphy by the use of composite sets.

The principal groups of equipment involved in such a system include the carrier sending and receiving equipment and filters at the terminals, the repeater amplifiers and filters at the intermediate stations, and the line equipment and pilot channel equipment at all points. In addition, power supply equipment and testing equipment are required at all points, and voice-frequency and signaling apparatus at the terminals.

The total amount of equipment involved in a typical carrier telephone system shown in Fig. 18, exclusive of the power supply, includes altogether about 188 panels assembled on racks equivalent to 14 bays[7] and occupying a total floor space, including aisle space, of about 84 sq. ft. If the three channels which the system ordinarily provides were obtained by regular wire circuits, the office equipment might amount altogether to about 36 panels and 1.7 bays, occupying about 10 sq. ft. Thus, in a typical case, about eight times as much office equipment, other than that for the power supply, might be required to furnish a given number of facilities by carrier telephony, in comparison with that needed for the equivalent number of ordinary wire circuits.

*Terminal Station Installations.* The principal equipment groups comprising a terminal of a type *C* system are indicated in Fig. 19. A typical assembly showing a majority of these equipment groups is given in Fig. 20. This does not include the signaling equipment, the pilot channel, or the power equipment. A rear view of this same assembly is shown in Fig. 21.

Returning to Fig. 20, the right-hand bay contains the apparatus comprising two channel terminals. The middle bay includes the third channel apparatus, and the terminal transmitting and receiving amplifiers and directional filters which are mounted in the upper portion. The box-like units on both bays are the band filters and directional filters. On the right-hand bay the upper of the panels with three vacuum tubes is the modulator-oscillator panel of one channel. Below it is the demodulator-oscillator panel of the same channel. Below the latter and in the center of the bay is the jack mounting strip which makes it possible to disconnect, or switch for testing purposes, the various units of the complete equipment. The demodulator-oscillator panel and modulator-oscillator panel, respectively, are the next two panels of the second channel. The terminal strips will be seen at the top of the bays. The metal shields surrounding the vacuum tubes are useful for mechanical protection only. The testing and power distribution equipment is located in the left-hand bay.

---

[7] A bay consists of two channel or I-beam uprights, ordinarily about 11½ ft. high, and spaced so as to mount unit panels 19 in. wide and of varying height.

The pilot channel apparatus at the terminal station, which is employed in regulating the performance of the system to compensate for variations in the line equivalents, is assembled in a typical installation as shown in Fig. 22. This apparatus may be located adjacent to the carrier terminal apparatus. The upper panel is the indicator unit with the indicator meter shown in the upper center of the panel. The panel immediately below this is the alarm panel with its voltmeter relay.

On both of these panels the associated vacuum tubes are mounted in the rear. The lowest panel is the oscillator panel with its vacuum tube and frequency control.

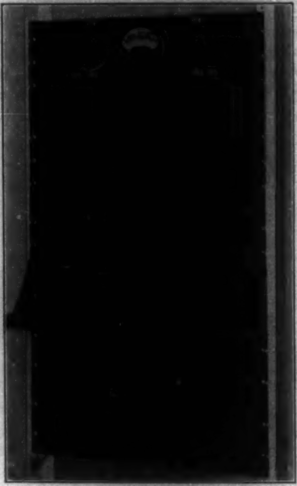

Fig. 22—Typical Assembly of Pilot Channel Equipment in Terminal Installation

*Typical Repeater Station Installations.* The equipment at each carrier repeater station consists mainly of the units indicated in Fig. 23. It is seen from this figure that the principal items are the line filter equipment, the amplifiers, the equalizers, the directional filters, and the jacks provided for testing and patching the equipment. Pilot channel equipment, power supply equipment, and testing equipment are also included. The amplifier equipment in each carrier repeater, other than the 15 TU auxiliary amplifier, is identical with the group amplifiers employed in each terminal station. The filters are also identical in type excepting that twice as many directional filters are required at each repeater station as at each terminal.

Fig. 23—Schematic showing Principal Equipment Unit in Carrier Repeater Circuit

A typical complete installation of two carrier repeaters with testing and battery supply circuits located in the bay at the left is shown in Fig. 24. The bottom panel on the left-hand bay is a reserve amplifier. Above this panel are the filament rheostats, telegraph instruments, jack panels, key panels for controlling the power supply, a panel containing a thermocouple and meter for testing, meters for reading currents and voltages, and finally the alarm relays. These last are operated by failure in the plate current in the amplifier tubes, thereby indicating when a tube burns out, or failure of either A or B battery supply.

Each repeater bay in this case, Fig. 24, contains an auxiliary amplifier to increase the gain in the high-frequency group. From top to bottom the panels are input filters, auxiliary filters, equalizers, auxiliary amplifier, two regular amplifiers separated by a jack panel, and output filters. The arrangement of filters and equalizers is chosen to minimize any tendency toward inductive feed-back effects between the output and input circuits of any one repeater as well as cross-talk between different repeaters on adjacent bays.

The pilot channel equipment at a carrier repeater station is similar to that employed at the terminal stations, excepting that the alarm and oscillator panels are not included. The alarm apparatus is omitted in this case, since it is not the practise to have the carrier repeater attendants readjust the carrier repeaters to take account of line changes, excepting when instructed to do so by the attendants at the terminal stations where the alarm apparatus is installed. The pilot channel equipment at each repeater station thus consists principally of an indicator panel associated with the transmission circuit in each direction, which is assembled with the other equipment as previously shown at the extreme right in Fig. 24.

*Line Equipment.* Fig. 25 shows the principal line equipment units which are closely associated in effecting connection between the high-frequency circuit of the carrier system and the voice-frequency line. This equipment consisting of the line filters, composite sets, and entrance and office load coils is mounted together in one assembly and located as near as practicable to the other carrier equipment. A method of assembly which is now under development is shown in Fig. 26. The bay shown contains the line equipment for two phantom groups.

FIG. 25—SCHEMATIC CIRCUIT SHOWING LINE FILTER EQUIPMENT FOR TYPE *C* CARRIER TELEPHONE TERMINAL. (PHANTOM GROUP)

This compact method of assembling and wiring the line equipment reduces the amount of office cabling required for the carrier and therefore reduces the possibility of inter-system cross-talk between carrier systems within the same office. The cross-talk requirements in an office may be more severe than on the pole lines because the level difference between circuits which operate on different pole lines terminating at the same office may be as much as 50 TU. As an aid in obtaining the required electrical separation all high-frequency wiring is reduced to a minimum by segregating and mounting together all line equipment associated with a single circuit. No high-frequency circuits appear at the toll testboard. The toll lines may be tested from the testboard by means of trunks between the testboard and the line equipment bays. All the carrier equipment is thoroughly shielded in such a manner that the separation between the equipment of any two systems is 120 to 135 TU.

FIG. 26—ARRANGEMENT OF LINE EQUIPMENT IN ONE ASSEMBLY FOR TYPE *C* CARRIER TELEPHONE. (FRONT VIEW)

The carrier line equipment at a carrier repeater station is generally similar to that at the terminal stations, as previously shown in Fig. 26. At each repeater station, however, this equipment is provided in the lines in both directions. Two types of low-pass line filters are employed at the repeater station, one adapted to circuits in which both carrier and voice-frequency repeaters are used and the other, which is less commonly used, for circuits employing only carrier repeaters and where the voice circuit continues through without a repeater.

*Voice-Frequency and Signaling Equipment.* The general function of the voice-frequency terminating equipment is to associate by means of a hybrid coil and network, the ordinary two-wire circuits in the telephone switchboard, including both talking and signaling functions, with the sending and receiving branches of each of the different carrier channels. The general arrangement of this equipment in the circuit is shown in further detail in Fig. 27. This includes the signaling equipment and makes provision for the connection of a balancing network.

FIG. 27—SCHEMATIC OF VOICE-FREQUENCY CIRCUIT FOR TYPE *C* CARRIER TELEPHONE SYSTEM

The use of a two-wire termination for the carrier system is necessary because ordinary telephone circuits at the switchboards, such as trunks, subscribers' lines, etc., are of the two-wire type and the cord circuits for interconnecting these are of this type. Hence, such a termination of the carrier system makes it possible to connect it to other circuits with the same apparatus and in the same manner as with ordinary telephone circuits.

FIG. 28—SCHEMATIC OF 1000-CYCLE RINGING CIRCUIT

The signaling apparatus consists of a 1000-cycle ringer of the type which is employed on long voice-frequency lines. This is connected to the voice-frequency terminal of the carrier system in the same manner as to other voice circuits. The use of 1000-cycle signaling with the carrier has been desirable in place of the more simple low-frequency signaling apparatus used on shorter lines, since frequencies less than 200 cycles are not efficiently transmitted.

Fig. 28 shows a simplified diagram of this type of ringer. The transmitted signaling currents as impressed upon the carrier channel are of 1000-cycle frequency interrupted at a speed of 20 interruptions per second. This ringing current supply is obtained either from 1000-cycle generators or vacuum tube oscillators. Such currents, while in the voice-frequency range and thus capable of being transmitted readily, form a signal of sufficiently distinctive character to permit separation from ordinary voice currents. Thus, practical freedom from voice interference with the receiving apparatus is obtained, since this apparatus is designed to respond to very small currents of this character but to discriminate sharply against other currents.

*Tests and Adjustments of Apparatus.* For the purpose of testing and "patching" (*i. e.*, interconnecting various equipment units in the carrier system), jacks are provided as previously shown in Fig. 19. The equipment which is employed for testing and adjusting the carrier apparatus provides means for measuring gains and losses at the various frequencies encountered and includes a supply of testing current at these frequencies. The general arrangement of the testing apparatus provided for measuring gains and losses is shown in Fig. 29. This is assembled with the other carrier equipment as previously shown in Fig. 20. It consists chiefly of means for switching a known loss in the testing circuit, an attenuator, and a calibrated thermocouple type measuring instrument for determining the value of the current transmitted through this apparatus. The 1000-cycle current is used for practically all testing of the terminal apparatus.

FIG. 29—SCHEMATIC OF TESTING CIRCUIT FOR TYPE *C* CARRIER TELEPHONE SYSTEM

The testing equipment at a carrier repeater station is arranged in a manner similar to that at the terminal stations, as previously shown in a general way in Fig. 29. It requires in addition, however, a carrier-frequency oscillator. Only high-frequency currents are transmitted through the carrier repeater, hence the 1000-cycle supply employed at the terminals where modulation and demodulation of these carrier currents occur, is not useful in testing the repeater equipment.

It is customary to make periodic tests of the equipment. On the longer circuits[8] each day the channels are "lined up" for the required over-all transmission equivalents. At less frequent intervals the vacuum tubes are checked for emission, the gains of the sending and receiving branches are measured, the carrier synchronism is checked, etc.

*Vacuum Tubes.* Two principal types of vacuum tubes are employed in this system. One of these is the so-called *L* tube. This tube has a filament circuit requiring a current of approximately 0.5 ampere with a voltage drop of 4.0. It has a $\mu$ of 6.5, and a normal plate current, when used as an amplifier with a *B* voltage of 130 and a *C* biasing potential of 8, of about 6.5 milliamperes.

For the output stage of the amplifier a higher capacity tube is employed. This is a so-called *O* tube having a $\mu$ of about 2.5, a filament current requirement of approximately one ampere at a voltage drop of 4.5. The normal plate current when used as an amplifier with a grid biasing potential of 22 and a plate potential of 130 volts is from 17 to 35 milliamperes.

In addition to the above the pilot channel uses a low-filament current tube. This tube has a $\mu$ of 8, a filament current of 0.060 ampere, and a filament voltage drop of 3 volts. The normal plate current when used as an amplifier with a grid biasing potential of 7 volts and a plate potential of 130 volts is approximately 0.003 ampere.

The tubes employ oxide coated filaments and have been designed to be especially long lived to meet daily 24-hour service requirements.

*Power Supply.* The power required for the carrier equipment is taken from the telephone office supply where this is adequate. Usually the 24-volt central office power plant is suitable for the purpose, and the 130-volt supply for the plate circuits of the tubes is taken from the same batteries provided for telephone repeaters if available. The carrier requirements, however, may amount to a substantial addition to the load on the power plant, particularly where several carrier systems are installed in a relatively small office.

The amount of power required for a typical carrier telephone system is substantially larger than the usual telephone power requirements for the same number of facilities. Each system terminal requires approximately 8 amperes at 24 volts and about 400 milliamperes at 130 volts. The power required for each carrier repeater amounts to about 4 amperes at 24 volts and 250 milliamperes at 130 volts. Thus the total power required for one three-channel system with two intermediate repeater stations would be in the neighborhood of 24 amperes at 24 volts and 1.3 amperes at 130 volts, amounting altogether to about 750 watts. This corresponds roughly to the amount of power consumed by about 80 telephone repeaters, so that the total power required for three such carrier systems would be about equal to that required for a cable repeater station having between 200 and 300 repeaters. Assuming 2 or 3 repeaters in a typical voice circuit, the carrier systems are seen to require over ten times as much power as voice circuits in providing the same facilities.

The best results are obtained with the carrier systems when very close regulation of this power supply is maintained. About ± 1 volt for the 24-volt supply and ± 5 volts for the 130-volt supply are desirable limits of variation. Means for obtaining such regulation are added as required to the existing power plant. In the larger offices this may consist of a duplicate battery with full-floating operation. In the smaller installations, a relay regulating circuit may be added which controls the filament current as the voltage varies from 20 to 28 volts. This consists of a sensitive voltmeter relay arranged with accessory relays to cut resistance in and out of the individual filament supply circuits as the voltage varies.

## DESIGN OF CARRIER APPARATUS

Many will, no doubt, be interested in the further technical details of some of the more important units of the carrier system.

In the development of the apparatus considerable preliminary work was necessary to determine the circuit requirements imposed upon the individual units. For example, preliminary to the design of the filters, laboratory studies were made to find what interfering frequencies might be expected in a channel and what attenuation the different filters must offer at various points in the frequency range, in order that the system should provide speech of satisfactory quality and freedom from interference. As a result of such work, it was possible to make the requirements of the filters no more stringent than absolutely necessary, thus keeping the cost down to a minimum while insuring adequate performance. Preliminary studies were also made on the other parts of the system such as modulator, demodulator, oscillator, etc. In the descriptions which follow, no attempt has been made to describe this preliminary work, the discussion being limited to the requirements imposed, and the circuits devised to meet these requirements.

*Modulator and Transmitting Oscillator.* A circuit drawing of the modulator is shown in Fig. 30. It may be considered that the function of the modulator is to translate the voice frequencies along a frequency scale to some assigned location in the band of frequencies to be occupied by the carrier system. The carrier frequency controls the location of the shifted voice band or sideband, and the oscillator, which provides this frequency, is made an integral part of the modulator unit. The modulating process requires a circuit element having a non-linear response characteristic to produce the sideband from a combination of the carrier and voice frequencies. In this circuit the three-element vacuum tube is operated to give this required characteristic.

---

[8] W. H. Harden, "Practises in Telephone Transmission Maintenance Work," *Bell System Tech. Jl.*, Vol. 4, Jan. 1925, p. 26-51.

Since the carrier is not transmitted in the type *C* system, each modulator and demodulator becomes a complete and independent frequency changing unit. As previously noted the frequency stability of each oscillator must be sufficiently good so that the carriers of the corresponding modulator and demodulator units will differ but slightly in frequency so as not to affect unfavorably the speech which is transmitted. In this connection both naturalness of the received speech and intelligibility must be considered. In the type *C* system satisfactory results have been obtained by holding the difference between the carrier frequencies of any two associated units due to all causes to within about 20 cycles.

The usual causes of frequency variation are fluctuations in the A and B battery supply, and changes in temperature and humidity. Vacuum tubes have to be replaced periodically and differences in the tube characteristics may cause a slight variation in the frequency.

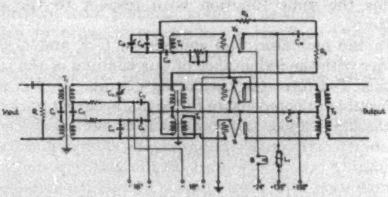

FIG. 30—SCHEMATIC OF MODULATOR CIRCUIT AND TRANSMITTING OSCILLATOR

The type of oscillator circuit was chosen to furnish the greatest frequency stability with variations in power supply, particularly in the plate battery. Fluctuations in the filament current are reduced by the use of ballast resistors to a point where they do not appreciably affect the oscillator frequency.

In order to maintain stability with temperature and humidity changes, it was necessary to develop circuit elements, (primarily the inductance in the oscillating circuit) which were not greatly affected by these variables. As a result the oscillators vary less than 10 cycles per second at the highest carrier frequency with power variations within the limits of plant maintenance, and have a frequency temperature coefficient of approximately 0.002 per cent per deg. fahr. This corresponds to about one cycle per second per deg. fahr. in the highest frequency units used in the type *C* system. The temperature difference between offices containing terminal equipment seldom exceeds 20 deg. fahr.

An extreme change in frequency of 20 cycles per second may be encountered with different tubes. Maintenance experience has shown that it is usually unnecessary to check the synchronization of the modulator and demodulator carrier frequencies more often than once a week, unless tubes are replaced or some other unusual circuit change occurs.

The modulating tubes are placed in a push-pull arrangement, and the carrier voltage is applied to both grids in phase and the suppression of the carrier frequency secured by a differential connection of the output transformer windings. It is difficult to suppress completely the carrier and a limit is set upon the amount which can be allowed on the high-frequency line without causing interference between systems. This limit requires that the carrier flowing out from the modulator should not exceed approximately 500 microamperes. With varying conditions of power, the balance of the modulator cannot be maintained absolutely constant, so that to insure meeting this requirement under the worst conditions it is necessary to adjust the balance under normal conditions to a point where the carrier has been reduced to about 150 microamperes at the output of the modulator. The sideband current flowing at this place in the circuit is ordinarily of the order of 2000 microamperes. Adjustment of the carrier balance is made by changing the condenser across one-half of the input circuit, and by selecting tubes.

A further requirement imposed on the modulator unit is that of gain stability. In order to maintain sufficiently constant transmission over a circuit there must be a high degree of inherent stability in all those units whose variations are not included in the indications of the pilot channel. The modulator and demodulator are the only units in this category.

In the modulator and demodulator the principal factors tending to cause instability of gain are the variations in plate and filament battery where these occur and changes in the tubes during their life. A characteristic behavior of the modulator described below has been used to advantage in minimizing this instability. The gain of the modulator for varying values of the carrier voltage passes through a maximum near the point where the grids of the modulator tubes are driven to a positive potential, with respect to the filament. The output from the carrier oscillator will increase with increasing plate potential, and due to the above characteristic may be made to compensate somewhat for the tendency of the gain of the modulating tubes to increase. Fig. 31 shows the change in gain of the modulator circuit when the plate potential of either the oscillating or modulating tubes is changed independently. With these arrangements the total variation in the modulator or demodulator gain, due to the fluctuations of power supply, does not usually exceed ± 0.25 TU. The possible variation due to tube differences is somewhat larger, approximately ± 0.7 TU. This is not serious since tubes are ordinarily replaced when a system is out of service, and the gain can be readjusted before the system is restored to operation.

Another requirement which the modulator must meet is one of transmission quality or equality in transmission gain at various frequencies in the voice band. The modulator should not limit the band of frequencies which is to be transmitted over the system. The characteristics of the transformers and the impedance in which the output of the modulator is terminated are the controlling factors in the quality of the modulator. A typical characteristic of modulator gain with frequency under ideal termination is shown in Fig. 32. In the type *C* system the effect of the band filter impedance is to cause a variation in this characteristic of approximately 5 *TU* at 2800 cycles.

The final requirement placed upon the modulator relates to the energy level which must be handled. It should not be possible to overload the modulator seriously with the amount of power produced by a subscriber's set at the transmitting toll testboard level. With a given modulator circuit, this requirement can be met by designing the input transformer with the proper turns ratio.

The following paragraphs give a more detailed description of the actual circuit which has been developed to meet the above requirements.

The voice-frequency circuit is through the hybrid coil to the terminals of the input transformer. The resistance placed across the input circuit is to improve the impedance terminating this branch of the hybrid coil, and thus improve the terminal impedance looking into the hybrid coil from the voice-frequency line. The condenser *C*–1 is inserted in series with the primary winding of the transformer to improve the transmission characteristic of the circuit at low frequency. This condenser resonates with the inductance of the primary winding, increasing the voltage across the primary at low frequencies where the modulator input circuit tends to become less efficient. The two windings of the secondary side of the transformer are separated by bypass condenser *C*–2, as they are at different potentials from ground, due to the series connection of the filaments of the vacuum tubes. The variable condenser *C*–3 affords a means of balancing the carrier-frequency potentials. Condenser *C*–4 is one-half the maximum capacity of *C*–3 in order that carrier frequency unbalance in either side of the circuit may be compensated for to a sufficient degree by means of the one adjustable condenser *C*–3. The voltages, $E_1$ and $E_2$, provide the grid bias for the modulating tubes *V*–1 and *V*–2. The condensers *C*–5 and *C*–6 provide a low impedance path around the source of biasing potentials for the carrier frequency, and condenser *C*–7 in the plate circuit performs the same function with respect to the plate battery.

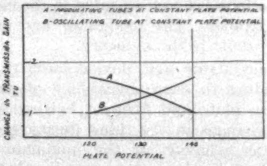

FIG. 31—MODULATOR GAIN—RELATION TO PLATE POTENTIAL

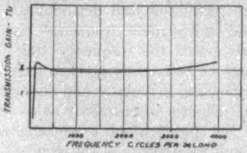

FIG. 32—MODULATOR GAIN—RELATION TO FREQUENCY

In the oscillator, the condensers *C*–8 and *C*–9 together with the inductance of one winding of the transformer *T*–4 form the oscillating circuit. *C*–9 is made adjustable to compensate for manufacturing variations in the inductance, and to provide in addition a certain flexibility in frequency adjustment. A grid bias for the oscillating tube is provided by the grid leak-condenser combination *G*. The plate battery is connected through the retardation coil *L*–1, which presents a high impedance to the carrier frequencies, and prevents their flowing through the plate battery. The carrier current in the plate circuit divides between two paths, one through *R*–2 the feed-back resistance to the grid circuit, and the other through *R*–3, the output resistance, and the transformer *T*–2 which impresses the carrier voltage on the grids of the modulating tubes. The filaments of the tubes in the modulator circuit are wired in series, and the current flow is regulated by a ballast resistor *B*.

Figs. 33 and 34 show the front and rear views of the modulator panel. The adjustable condensers which control the carrier frequency and the carrier balance are accessible from the front of the panel. In the rear view, the oscillator circuit occupies the left-hand side of the picture. The oscillating transformer is in the upper left-hand corner, with the oscillating condensers directly below it. The feed-back and output resistances are connected across the top of the panel. The oscillating tube is left of the three tubes, and the carrier input transformer is below it. The voice input transformer is to the right of the carrier transformer, and the output transformer is located in the upper right-hand corner. A metal cover fits over the complete panel at the back to provide electrical shielding and mechanical protection. All outside connections to the panel are made through the terminal block in the lower right-hand corner. Wires supplying power, together with those which are at a low a-c. potential with respect to ground, are run in a cable, while wires at a high a-c. potential are run directly from point to point in as short a path as possible in order to reduce losses resulting from the capacity of these wires to ground.

Fig. 33—Assembly of Modulator Panel. (Front View)

*Demodulator and Receiving Oscillator*. The circuit of the demodulator shown in Fig. 35 is in many respects similar to that of the modulator. The function performed by the demodulator is also similar, being a translation from a high-frequency band to a lower instead of the reverse.

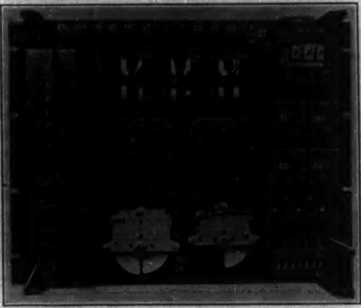

Fig. 34—Assembly of Modulator Panel. (Rear View)

The oscillator which supplies the carrier to the demodulator is of the same type as the modulator oscillator, and has been discussed in connection with that circuit. No adjustable feature for balancing the carrier is required in the demodulator circuit. The carrier suppression needed in addition to the suppression inherent in the balanced circuit is provided by the low-pass filter at the output. If the carrier is not sufficiently suppressed, it will pass into the voice circuit or across the hybrid coil into the associated modulator, causing, in some channels, an objectionable beat tone.

The transmission stability of the demodulator is obtained by the same methods used in the modulator since the performance of the two circuits is similar, and the transmission quality requirement is essentially the same for both units. A typical demodulator characteristic is shown in Fig. 36. This characteristic at the higher frequencies is controlled by the low-pass filter.

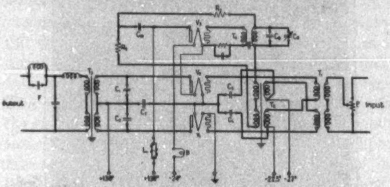

Fig. 35—Schematic of Demodulator Circuit and Receiving Oscillator

One feature which is required with the demodulator, but not with the modulator, is a variable control of the transmission gain of the circuit. Due to the unequalized transmission of the line section adjacent to the terminal, or other differences in the channel equivalents, the three sideband currents normally arrive at a receiving terminal with unequal strength. A potentiometer controlling the gain of the demodulator permits of an equalization of the over-all losses on the three channels.

In the following detailed description of the demodulator circuit, other minor differences between it and the modulator may be pointed out:

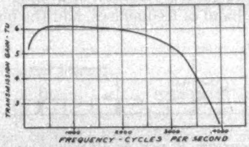

Fig. 36—Demodulator Characteristic—Gain and Frequency

The sideband frequencies enter the demodulator, passing to the potentiometer *P*–1, which controls the amount of current to the input transformer *T*–1. The position of the carrier input transformer *T*–2 is somewhat different in the demodulator circuit as compared to the modulator circuit, due to the difference in the high-frequency characteristic of the *T*–1 transformers. In the modulator, this transformer must be designed primarily to transmit voice frequencies. It has a comparatively large capacity to ground which would reduce the effective carrier voltage on the tube grids if it were placed in the same circuit position as is the demodulator transformer. The function of most of the circuit elements is evident from the previous description of the modulator. The $C$–1 and $C$–2 condensers provide a low-impedance path for the carrier frequency. They are necessary here because the transformer $T$–3 designed for high efficiency at voice frequencies has considerable leakage inductance which would present a high impedance to the carrier in the plate circuit if the condensers were not provided. Of course, for the maximum gain, the impedance of this circuit should be a minimum at carrier and sideband frequencies. At the output, a low-pass filter structure $F$ provides for the suppression of the unwanted products of demodulation.

FIG. 37—ASSEMBLY OF DEMODULATOR PANEL. (FRONT VIEW)

A front view of the demodulator unit is shown in Fig. 37. The panel layout and general appearance is similar to that of the modulator. The two dials shown control the demodulator input and the oscillator frequency, respectively, as indicated in these figures.

*Filters.* The general function of a band filter is the selection of a band of frequencies, and the protection of this band from interfering frequencies located on either side. The filters determine what band width is transmitted, and thus to that extent, they control the quality of speech which may be obtained through the carrier circuit. The type $C$ system transmits a band corresponding to approximately 200 to 2700 cycles per second in the voice range.

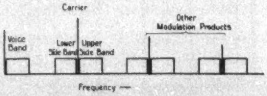

FIG. 38—FREQUENCY RANGE OF PRODUCTS OF MODULATION

In considering the requirements imposed upon the band filters it is necessary to keep in mind[9] the fact that the modulator produces not only the particular sideband which is to be transmitted but also an unwanted sideband of the same volume as the wanted sideband and equal to it in width, located on the opposite side of the carrier frequency. In addition to these products of modulation there are produced other frequency bands, the important ones occupying sideband positions about the harmonics of the carrier frequency. See Fig. 38.

The first requirement on the band filters is imposed by the need of suppressing the unwanted sideband to prevent distortion when the carriers are out of synchronism. The tests mentioned above in connection with the oscillator frequency stability were made with but one sideband transmitted. If both sidebands are transmitted the carriers must be exactly in synchronism or a "wobble" due to the demodulation of both sidebands can be detected. As this carrier difference increases, one sideband must be suppressed by an increasing amount. For a carrier frequency difference of about 20 cycles, it is necessary to suppress the unwanted sideband about 40 TU, thus reducing it to about 1/100 of the strength of the wanted sideband in order to eliminate completely this type of distortion. This requirement can be met by providing the necessary attenuation in either the transmitting or the receiving band filter, or by making the sum of their attenuations equal to 40 TU.

In a multi-channel system in which the transmitted sidebands are close together, the suppression of the unwanted sideband is necessary for another reason. The unwanted sideband from one channel overlaps the wanted sideband of an adjacent channel and would be demodulated and appear as "cross talk" into this channel if it were not suppressed by the transmitting band filter. The suppression needed is determined by the amount of interference which can be tolerated from one channel to another. It has been found that to meet this requirement the transmitting band filter must suppress the unwanted sideband about 60 TU. The other modulation products mentioned above must also be reduced by the transmitting band filter to a value which will not cause interference in any channel into which they might pass. The discrimination requirement for these frequencies is less severe because the magnitude of these modulator products is not so great.

A particular termination is required at the end of the filter which is connected to the modulator. In order to get the maximum sideband power out of the modulator used, the impedance of the associated band filter, seen from the modulator, must be made low over the range of voice frequencies.

With the channels placed close together and coordination of different types of systems depending upon the channel locations, it is important that the band filters remain constant after manufacturing and that all filters of the same type be manufactured to meet close requirements. For proper coordination between systems, it has been found desirable to keep all the channel bands within ± 125 cycles of an assigned location. In the higher frequency channels, this means that the filters must be manufactured to a frequency accuracy of the order of ½ of one per cent.

---

[9] R. V. L. Hartley, "Relation of Carrier and Side Bands in Radio Transmission," *Bell System Tech. Jl.*, Vol. 2, April 1923, pp. 90-112.

The attenuation requirements for the receiving band filter are somewhat different from those of the transmitting band filter. The purpose of the receiving band filter is the suppression of the frequencies of the adjacent channels as they are received over the line. In contrast to the transmitting filter, which must suppress the unwanted frequencies produced in its own channel, a filter with somewhat different characteristics could be used, therefore, for a receiving filter. While the requirements were determined separately for the receiving and transmitting filters, it was desirable in the interest of manufacturing economy to build both alike, setting requirements on the basis of a double purpose filter. Thus, this filter had to provide attenuation at each frequency to meet the more severe of the requirements for either the transmitting or the receiving position. Fig. 39 shows the transmitting characteristic of a typical filter designed to meet the requirements outlined above.

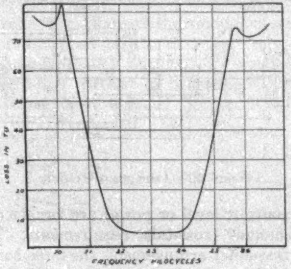

FIG. 39—TYPICAL BAND FILTER CHARACTERISTIC

As has been explained, the grouping of the channel bands in opposite directions requires the use of so-called directional filters at terminal and repeater points These filters occur in the circuit in pairs, each pair consisting of one high-pass and one low-pass filter. The cut-off point of the filters is determined by the type of system in use—*C–S* or *C–N* and its corresponding "grouping point." At repeater points, the filters are split for each direction in order to provide selectivity at both the output and input circuits of the amplifiers.

Considering the closed circuit through the two amplifiers and the four directional filters, the attenuation in this loop must be considerably greater than the sum of the gains of the two amplifiers at all frequencies. In the regions outside of the carrier frequencies, the margin between attenuation and gain is made about 10 TU. For frequencies in the carrier range, this margin must be still greater to prevent distortion which becomes objectionable when circulating currents of any size are allowed to exist. This "feed-back" effect will also affect the repeater input impedance, and because of the necessity for closely controlling this characteristic, the margin between gain and attenuation is not permitted to be less than 25 TU at any frequency used for transmission in either direction. The impedance of these filters on the line side must match the line impedance closely in order that no considerable reflection of the carrier currents can take place at this junction point.

As previously mentioned, due to modulation, the output of an amplifier contains other frequencies in addition to those which compose the input, so that cross-talk is to be expected between some of the channels. The amount of cross-talk which appears at the far end depends upon the ratio of the sideband currents to the interfering currents produced in the amplifier, the measurement being made at the repeater output. The near-end cross-talk, however, is dependent upon the level difference between the strong output of the one amplifier and the weak input to the other. Those frequencies which may give trouble in the channels at the near end enter the returning circuit at the amplifier input,—a point where the sideband level is very low. To put the near-end cross-talk on the same basis as the far-end, the output directional filter must introduce enough attenuation in its non-transmitting range to make up this level difference. This attenuation is increased until the near-end cross-talk due to this cause is appreciably less than the far-end.

The output current of one amplifier may be 30 TU or more stronger than the input current to the amplifier for the opposite direction, and the directional filter at the input of this second amplifier must offer sufficient attenuation to the output currents of the first so that they will not contribute materially to its load.

Fig. 40 shows the selectivity characteristics of the two directional filters.

A pair of filters having important functions is the line filter set which, as has been noted, acts to separate the carrier currents from the regular speech currents on the common line circuit. It consists of a high-pass and a low-pass filter paralleled on the line side. Currents entering these terminals from the line circuit pass through the high-pass circuit, to the carrier apparatus, or through the low-pass circuit to the circuit terminal or repeater. The transmission characteristics of these filters are shown on Fig. 41. It will be noted that frequencies above approximately 3300 cycles are transmitted in the high-pass circuit, and frequencies below about 2800 cycles are transmitted through the low-pass circuit. In addition to those which are normally in use for carrier transmission, it is common to equip a few line circuits with line-filter sets. This makes it readily possible in case of an emergency, or for other reasons to use the spare wires thus equipped for carrier transmission.

Non-linear effects may be produced in the coils and condensers in the circuit. The design of the filter parts must be made so that these effects will be a minimum. This requires the use of non-magnetic cores in the coils, and also that the containers be of non-magnetic material. Condensers in magnetic containers must be located so that they will not lie in the field of the coils, and thus contribute to the modulation products. The modulation in the line filters, telegraph composite sets, and office and cable loading units must also be considered.

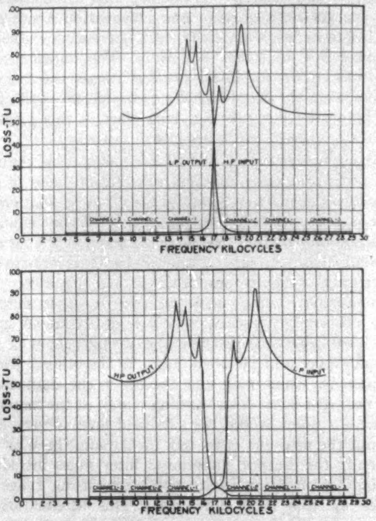

Fig. 40—Typical Directional Filter Characteristics

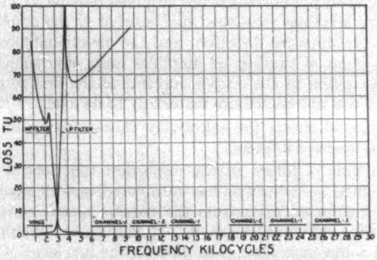

Fig. 41—Typical Line-Filter Characteristics

As already mentioned, care has to be exercised in the mounting of filters belonging to different systems in the same office, so that no cross-talk will be introduced from one system into another. A considerable level difference may exist between two filters of different systems, and it may be desired to mount these filters on adjacent bays. In order that the cross-talk between these two systems may be kept within desirable limits, the separation between the filters must correspond in attenuation loss in some instances to the order of 120 TU, or one part in a million. To meet this exacting requirement, the filters are totally incased in sealed copper boxes, the leads being brought out through small holes to terminal blocks.

*Amplifiers.* As previously mentioned, the amplifiers employed with the type *C* system at the terminals are identical with those used with the repeaters at intermediate stations. Therefore the following is applicable to both cases:

The number and size of tubes needed to deliver the necessary output level or power are largely controlled by interchannel cross-talk requirements. With the grouping frequency arrangement, the three bands which transmit in the same direction are amplified in a common circuit. In passing through the common amplifier, the different sideband frequencies must not react upon each other to produce other frequencies of sufficient magnitude to cause interference. For example, second harmonics of the lowest band frequencies lie within the range of the highest channel in the lower group. If these harmonics are permitted to become too great, troublesome noise will be present in the highest channel when speech currents flow in the lowest. In order that this interference or cross-talk may not become excessive, the tubes used in this amplifier must be made of ample power capacity. This example of interference caused by the second harmonic shows the desirability of using a push-pull amplifier in carrier repeaters because of its property of balancing out second order effects, which in a single-tube or unbalanced circuit are the largest of all the modulation products at the usual loads.

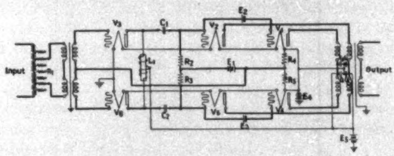

Fig. 42—Amplifier Circuit

The currents from the three channels enter the carrier amplifier shown in Fig. 42. The circuit consists of two stages; the first stage of two tubes, the second of four of higher power rating. The gain is controlled in 2-TU steps by the adjustable potentiometer in the input. The gain frequency characteristics for different potentiometer settings are substantially flat within a small fraction of a TU over the range of any channel.

The amplifiers for the two directions are of slightly different design, each amplifier being arranged for a flat characteristic over its own group of frequencies. It has been stated that the load capacity of the amplifier is limited[10] by the modulation products which increase with the load. Fig. 43 shows the amount of second and third harmonics produced in a typical repeater with varying single-frequency output. By connecting the tube in push-pull instead of in parallel, the second harmonics have been reduced by about 15-20 TU.

Fig. 44—Map showing Carrier Telephone Systems Throughout Bell System

Other products of modulation, as well as the second and third harmonics, increase with the output and thus the power which can be taken from the amplifier under the operating conditions is limited, as these effects are likely to result in interchannel interference.

When the alternating voltage applied to one grid is positive with respect to the filament, that on the other grid is negative. Since the even order products are proportional to an even power of the input voltage, these currents will flow through the high-side winding of the output transformer non-inductively producing no flux in the transformer, and hence no current in the low-side windings. To realize this ideal condition, the two currents flowing in the output transformer windings must be equal in amplitude, and 180 deg. out of phase. Since the plate current is a function of a number of tube constants, like amplitudes can be obtained in several ways. Tubes which will give the same harmonic current may therefore be selected; that is, tubes in which the net effect of the several factors is the same.

## Conclusion

*Use in Telephone Plant.* The carrier systems are meeting successfully and economically the requirements of long distance telephone service. From what has already been written, however, it is evident that by its nature, the apparatus is complex and to a fair degree expensive, so that for the relatively short distances, it is cheaper to string additional wire. The exact distance beyond which it is more economical to employ carrier methods is obviously dependent upon the circumstances surrounding each particular case. Systems are operating for distances of 150 mi. and upwards.

Often where there are longer haul continuous physical circuits on the same line traffic growth requires additional circuits for the shorter distances. In such cases, it is not uncommon to break up the long-haul physical circuits into sections to satisfy the short-haul circuit growth and to install a carrier system to meet the long-haul needs.

---

[10] F. C. Willis and L. E. Melhuish, "Load Carrying Capacity of Amplifiers," *Bell System Tech. Jl.*, Vol. 5, October, 1926, pp. 573-592.

The growth of the use of carrier systems has already been pictured. How the systems are distributed over the lines of the Bell System is shown on Fig. 44. The heaviest density of use occurs in the middle and western sections and in general where the circuit demand and growth have not reached the large figures required to justify the installation of toll cables. The section west of the Mississippi, in particular, is a promising field for the application of carrier systems.

*Future.* While the type *C* system satisfies those circuit-growth demands for moderate- and long-haul, there has remained undeveloped a considerable field for carrier methods over the shorter distances where hitherto only wire stringing has been economical. Very recent developments have resulted in the trial and early field applications of a simple single-channel carrier telephone system designed particularly to meet these shorter-haul demands and thereby to secure the greatest practicable economy in providing facilities by carrier methods in the Bell System. Naturally it is finding its most extensive use in the sections of the telephone plant where the shorter circuits predominate. Because of the fact that the type *D* system development is only now being completed, it was thought desirable in the present paper to confine attention to the long-haul system (type *C*) and to defer the presentation of the detailed information on the short-haul development until a somewhat later date.

While since the beginning of their use, about ten years ago, considerable progress has been made in the development and application of these carrier systems, there is still much to be done in the matter of simplifications and further use of the high-frequency spectrum. Automatic pilot channel arrangements are being tested whereby manual maintenance costs can be reduced. Further developments are anticipated in the matter of transposition arrangements to permit an open-wire line to carry multi-channel long-haul carrier systems on most of its pairs. While the systems now in use in the field employ frequencies no higher than approximately 30,000 cycles, frequencies considerably higher than this can undoubtedly be economically employed.

## Bibliography

### ARTICLES RELATING TO MULTIPLEX CARRIER TELEPHONY AND TELEGRAPHY

With no pretensions as to completeness, the following more important papers and articles relating to multiplex carrier telephony and telegraphy are offered as an addition to the bibliography which forms part of the Colpitts-Blackwell paper. Reference should be made, therefore, to the latter for articles published prior to 1921.

*Use of High-Frequency Currents for Control*, C. A. Boddie, A. I. E. E. Trans., 1927, Vol. 46, p. 975.

## Discussion

**C. S. Demarest:** Certain points in connection with the development of the equipment referred to in the paper are perhaps of sufficient interest to warrant a few further remarks.

The amount of carrier telephone equipment in the plant of the Bell System is becoming quite large in those sections of the country in which open-wire circuits predominate. Approximately 150 systems are now in service on the longer circuits and the number is growing rapidly. In some installations this equipment, together with the repeaters and other associated apparatus of generally similar character, may comprise a considerable part of the total equipment other than the switchboards.

The satisfactory functioning of this equipment is vital to the service which the carrier system performs, since it is the basic means of providing the speech channels for additional facilities. Certain of the wiring and equipment arrangements affect both the performance of the systems and their practical application. Consequently, the details of these arrangements have required careful consideration.

Some of the problems have had to do with the matter of providing effective electrical separation between apparatus units and between wiring, while at the same time permitting assembly arrangements which would be desirable for plant use. The relatively high frequencies and large power-level differences occurring in the carrier systems, as compared with those encountered at voice frequencies, have necessitated some special provisions in this regard. Level differences as great as 50 TU, amounting to a power ratio of 100,000 to 1, may sometimes occur between apparatus units desired to be located closely together.

With ordinary telephone apparatus it has often been the practise to wire many individual apparatus units to terminals at a central distributing frame, in order that interconnections between units might be readily changed. With that part of the carrier apparatus involving high-frequency currents it has been desirable to modify this practise. The line equipment, for example, has been grouped together in one assembly and none of the individual apparatus units in this group has had wiring brought out to the distributing frame. This has reduced considerably the total length of the wiring per circuit within the central office, with consequent reduction in the losses and impedance variations which may be caused by this wiring. This has been a factor of some importance at carrier frequencies because of the relatively large capacitance per unit length of the office wiring as compared with the outside line wires.

Crosstalk between circuits which might occur in the wiring between apparatus units in this portion of the equipment is effectively prevented by using shielded cable. Special precautions are needed at the points in the high-frequency circuits where the conductors may be exposed electrically, even to a small extent. The connections between the lines wires and the group of apparatus comprising this line equipment are made at the top of the equipment bay by soldered connections to terminals arranged in rows less than ½ in. apart. Ordinarily, in voice-frequency circuits, the conductors in different phantom groups may be connected to adjacent rows of such terminals. In the case of the high-frequency carrier circuits, however, it has been found desirable to use only alternate rows of terminals, the intervening rows being strapped together and connected to ground so as to form a shield between the others. Somewhat similar precautions have been found desirable in the wiring to the jacks in the jack panel for the line equipment.

In order to permit mounting compactly the apparatus in the high-frequency portion of the circuit, it has been necessary to employ shielded units such as coils, etc. This has made it possible to locate such coils for separate circuits both on the front and back of the same panel. In the case of the filters, satisfactory shielding has been obtained only by assembling these in sealed copper cans, the ordinary removable can covers used in other telephone equipment being subject to sufficient leakage field at the junction point between cover and panel to make them unsuitable for filter use. With this type of shielding, the filters have been satisfactorily free both from crosstalk and from variations in characteristics due to the effects of surrounding apparatus of different types.

In caring for such requirements it has not only been necessary that the carrier telephone equipment should function satisfactorily of itself, but it has been essential that it should be capable of being correlated readily and flexibly with the circuits and equipments of various types in the plant. It has been advantageous to employ for the carrier equipment the panel-type mounting and assembly arrangements generally similar to those now used for much of the other toll equipment. This has not only effected the desired uniformity in design, but has provided features particularly adapted to the carrier equipment itself, as in the case of the line equipment just mentioned. It has also afforded the desirable features of economy in floor space and accessibility for maintenance purposes.

**C. W. Green:** One phase of this problem, the development of carrier systems, which I might amplify, is the question of crosstalk. The crosstalk between carrier systems on the same pole line is taken care of quite generally by transpositions. There is another problem, though, the crosstalk between the channels of a system, which requires attention in the development of apparatus for the carrier systems.

The currents of the three channels pass through a common amplifier and the characteristics of an amplifier are such that there are produced in the output, harmonics of the input frequencies, frequencies which are the sum and differences of the input frequencies and other combinations of the input frequencies. The design of the amplifier has to be such that these products of modulation are kept down very considerably in order that the crosstalk between channels will not be troublesome. This requires that, by care in the design and operation of the carrier amplifier, these products of modulation be maintained at lower levels than are usually necessary in voice-frequency amplifiers.

**D. I. Cone:** As shown on Fig. 44, much use has already been made of type C carrier telephone systems on the Pacific Coast and to points east now comprising 31 systems with 26,600 channel-miles of circuits. Extensive additional applications are now being engineered. These systems have made a splendid record in actual performance and providing for the large growth in long-distance telephone service pending the orderly development of the cable network. One of the two leads between San Francisco and Los Angeles is now carrying eight systems (24 channels) on two crossarms for a distance of 250 mi. This unusual density of concentration was secured in this case without sacrifice of the high quality and freedom from inter-system crosstalk.

# Superimposed High-Frequency Currents
## for Circuit-Breaker Control

BY LEON R. LUDWIG[1]
Associate, A. I. E. E.

*Synopsis.—On railway or polyphase power systems having a multiplicity of parallel lines, there are unique possibilities in superimposing on the lines a frequency of the magnitude of 500 cycles, (together with the consequent apparatus), to gain selective protection under all fault conditions. The principle suggested is to measure the impedance of the power system with 500-cycle current and high-frequency relays, so placed that under abnormal conditions the impedance of a faulty line, as measured by the relays protecting that line only, is sufficiently low to cause circuit breaker operation.*

*The advantages of such a protective system would be:*

1. *Perfect selectivity between parallel power lines, such that a faulty line may be isolated without disturbing other lines.*
2. *Instantaneous operation.*
3. *Simultaneous operation of protective breakers at the two ends of a faulty line.*
4. *Protection of the line against short circuits or faults, but the avoidance of breaker operation on heavy overloads when the current rush may be greater than at short circuit.*
5. *A measure of the continuance of a fault, permitting automatic reclosing of circuit-breakers.*

*This super-frequency control system brings to light a number of refreshing conceptions, and while it is not completely developed at this time, sufficient experimental work has been done to warrant presenting the results as a matter of technical interest.*

### THE CIRCUIT-BREAKER CONTROL PROBLEM

ANY relay or other type of apparatus called on to control circuit-breakers automatically, must meet an increasing number of rigorous qualifications. In addition to causing the breaker to operate if excessive currents arise in the system to which it is applied, there is a number of other requirements which are essential, or desirable, all or some of which must be fulfilled, depending on the system.

First, the system to be protected may consist of parallel feeders, any of which is liable to a fault. Should one of the parallel feeders become faulty at any point, it is essential that this feeder be disconnected from the system by opening circuit-breakers at both of its terminals, but parallel feeders should remain undisturbed. This desirability of perfect selectivity between parallel conductors may, if the fault occurs near one terminal, tax the ordinary relay beyond its limit of differentiation.

An increasingly important requisite is the high speed of both relay and circuit-breaker operation. On power systems, the ability of protective apparatus to isolate a fault rapidly is an important asset in maintaining stability. The dynamic stability may be greatly increased if the time required to remove a fault is somewhat less than that required for synchronous machinery to shift its phase angle appreciably. In case of nearby parallel telephone lines, telephone interference may dictate rapid isolation.

On many systems having a widely divergent load demand, heavy-load currents may exceed short-circuit currents if the short circuit occurs with the minimum of generating capacity connected to the line. The control equipment must act to isolate the short circuit, but should not open the loaded line, a condition which precludes the use of plain overload relays.

There are other desirable features of relaying systems, three of which may be mentioned. Circuit breakers are frequently tripped to temporary faults, in which case, if the relay could determine the nature of the fault, the breaker might be again closed and normal conditions restored without the need of an operator. Automatic reclosing would be particularly advantageous if, with the circuit-breaker open, the relay could determine whether or not it might safely be reclosed. From the standpoint of telephone interference, a further requirement is the simultaneous operation of the circuit-breakers which are to open, or the avoidance of "cascade" operation. The third feature is a relay system which could be set and tested for proper operation without the necessity of actually placing a short circuit on the power system.

A combination of the above problems has so strained the usual concepts of relay procedure that an entirely new basis of circuit-breaker control is desirable and may be found in the application of a superimposed high-frequency current system. The purpose of the new system is therefore to extend the limitations naturally imposed by the use of normal frequency relays.

### DESCRIPTION OF THE SYSTEM

The 500-cycle system consists essentially of a source of high-frequency power, a means for introducing it into the lines to be protected, means for obtaining selectivity in case of parallel lines, and the circuit breaker operating relays. The system is equally applicable to a single-phase railway system or a polyphase power system. An application to a single-phase system may be described first for simplicity. In Fig. 1 is shown a grounded single-phase system, which may be a railway network. There are two parallel contact lines supplied with power from transformers located in three substations. A circuit breaker is placed in each end of each contact line.

The 500-cycle current is introduced into the system by a connection from the generator or power source to the ground side of the main transformer. The other

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

terminal of the power source, which is usually a small high-frequency synchronous generator, is connected to the ground. A high-frequency power source is necessary at each point in the network where power current of normal frequency is supplied. To prevent the high-frequency generator from being short-circuited by this connection, a resonant device consisting of a condenser in parallel with an inductance is placed in the main power circuit between the point of connection of the generator and ground. The condenser and inductance are each designed to have the same reactance at the high frequency, and therefore if their resistance is low, their combined impedance will be very high. Currents of normal frequency pass easily through the inductance, which has in itself a very small impedance. The parallel circuit may be referred to as a "blocking shunt."

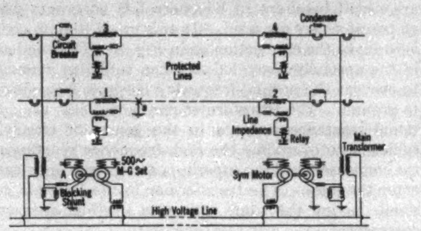

Fig. 1—Protective System Applied to a Single-Phase Network

In order to gain selectivity between parallel lines, a device similar to the blocking shunt, though very much smaller, is placed in each end of each line. Its function is purely as a line-impedance at the high frequency, with the advantage that considerable impedance may be obtained by the use of a very small reactor in this way. A high-frequency current will circulate in the parallel line-impedance which is proportional to the high-frequency current in the line. The relay itself may therefore be connected to a current transformer placed in the condenser branch of the line-impedance. The condenser will carry very little of the power current, which means that the relay will function solely on high-frequency current proportional to that in the line.

### Description of Operation

Normally, with no fault or load on the contact lines, the generated voltages of the high-frequency machines are equal and opposed. These machines will synchronize and there will be no appreciable current flowing in the contact lines. To further aid in keeping the voltages opposed, the generators are driven by normal-frequency synchronous motors, which will maintain an almost constant phase position.

If a ground occurs at (a) on one of the lines, high-frequency current will flow from the generator through the main transformer to the contact line, then to ground through the fault, and return. An appreciable current will therefore circulate in the resonant line impedance (1) and (2), sufficient in magnitude to trip the corresponding relay. Some current will also flow from the generator *B* through the line (3-4), but this current will be less in magnitude because it must pass through three line-impedances instead of one as in the former case. Then the current in the parallel line will not be sufficient to trip the relays at (3) and (4). For similar reasons, the remaining relays in the adjacent lines will not be tripped.

In case some form of load is connected to one of the contact lines—a locomotive for example—high-frequency current will flow to ground through the load, but will not be sufficiently great to trip any of the relays because of the load impedance. It is fundamental that the high-frequency current always provides a means of measuring impedance regardless of the network. Normal speeds of rotating machinery are so much below the high-frequency synchronous speed that practically no counter-voltage is generated at this high frequency. It is also usually the case that the blocked impedance of the load is high in comparison with line impedances, which means that there is a good margin of differentiation between heavy loads and short circuits. In brief, the high-frequency system may be looked upon as a network equivalent to that of the normal frequency except that all normal frequency rotating apparatus may be considered as blocked.

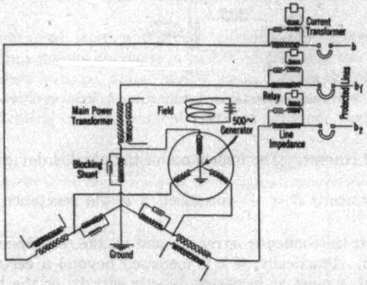

Fig. 2—Protective System Applied to a Three-Phase Network

### Polyphase Application

The means of using this apparatus on a polyphase system is shown in Fig. 2. The high-frequency generators must now be polyphase. Their current may be introduced in the neutral side of the main transformer winding, three of the blocking shunts per power source being required. It is assumed that the main transformers are connected in star with a grounded neutral. Otherwise, the method of connection will be given later. If there are parallel lines, line impedances must be used as before. The principle of operation is the same; namely, that the high frequency is introduced and the line impedances are so placed that the impedance measured by a given relay is the correct impedance to cause that relay to trip, provided there is a fault on the line it protects. By tracing the path of current in the diagram, it can be seen that a short circuit between lines ($b_1 - b$) will cause a relay-actuating current to flow.

### DISCUSSION OF SPECIAL PROBLEMS

The system depends so largely for its successful operation upon the parallel resonant circuits that special mention of their properties will be made. If the condenser and reactance are resonant at the chosen high frequency—500 cycles for example,—then at 25 cycles the reactor will have one-twentieth of its high-frequency reactance. The condensive reactance will be increased twenty times at normal frequency, or 1/400 of the load current will pass through the condenser. The reactor must be designed, therefore, to carry the load current. The impedance of the parallel device is very nearly $Z = \frac{x^2}{r}$ in which $x$ is the reactance of either the condenser or reactor and $r$ is the resistance of both. Practically, if $x$ is increased beyond a certain point, $r$ must be increased directly with it, or the impedance will vary as the first power of the reactance.

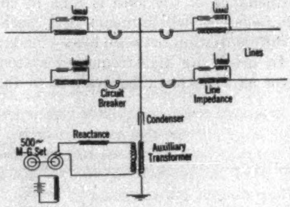

FIG. 3—SPECIAL METHOD OF INTRODUCING AUXILIARY CURRENT INTO A LINE

It is easy to obtain an impedance of a few hundred ohms, which is sufficient for the blocking shunts, with a comparatively small reactor and a single condenser unit. The line impedances require about 40 ohms, which is very easily obtained.

In certain networks the blocking shunts may serve another function than previously explained. It may be desirable to subdivide a complicated system into a number of simple high-frequency systems in order to measure the impedance of the simplified systems. The ability to do this by inserting the blocking shunts at predetermined division points, is very important because the most involved network may be resolved into a number of small networks for the purpose of facilitating high-frequency relay protection.

There is a special problem also in getting the proper connection of the high-frequency power to the protected lines. To avoid insulation to ground of the high-frequency apparatus the connection in Figs. 1 and 2 is made on the low side of the transformer. This method is feasible because the reactance of a large power transformer is low. The transformer reactance is, in fact, helpful because the high-frequency system should be laid out in such a way that short circuits on the protected lines are loads, not short circuits, upon the protective system. In some cases, however, there are circuit breakers to be controlled at points where no transformers are used. In this event, the procedure is to make the connection as in Fig. 3. The condenser in the specially provided tap has sufficient reactance to prevent the normal-frequency currents from flowing to ground. The transformer reactance, plus the additional reactance inserted in the generator circuit, is sufficient to overcome the high-frequency reactance of the condenser, and the superimposed current may easily enter the lines. The transformer in the figure is very small, having the same rating as the high-frequency generator.

In three-phase systems, the transformers may be delta-connected, or there may be no ground. A high-frequency ground may be provided by connecting the neutral to ground by means of a condenser. In case of the delta-connected transformers, the method of introducing the current shown in Fig. 3 may be used in three-phase form.

There are a few special considerations in the use of 500-cycle synchronous machines and the steps taken to keep them in phase opposition. The power required from these machines is that necessary to operate the relays and supply the high-frequency line loss. Two kilowatts are ample for a large system. Machines of this frequency synchronize quite as well as those of lower frequency, provided too much reactance is not present between the two. The length of a section of line to be protected is often sufficiently short so that the reactance between generators will not cause synchronizing difficulty. In case it does, however, the high-frequency voltage may be stepped up by means of a transformer in order to decrease the effective reactance. Normally the high-frequency potential need not be more than 250 volts, though it may run much higher on long lines.

Fig. 1 shows the generators driven by synchronous motors connected to the main power feeder. If this connection is made, there are two closed systems interconnecting the motor-generator sets at two frequencies. If there is a difference in the phase angles of the voltages of power frequency at the two motor-generator sets, there must be flexibility in the inter-connection. This flexibility should occur in the power-frequency side of the motor-generator sets and may be obtained by the use of a flexible coupling between the two machines of the set, or by placing reactance in series with the synchronous driving motors. Either of these devices will aid in keeping the high-frequency voltage closely in phase. A synchronous driving motor has been selected because it permits the auxiliary generators to supply power at constant speed and frequency. The constant frequency is essential to prevent the parallel shunts and line impedance from departing from resonance.

The final component of the system needing special discussion is the relay. In Fig. 4, a 500-cycle mechanical relay is shown which has two elements connected in series. The function of the relay is to trip if a rapidly rising current of sufficient value is passed through it. This limitation of a rapidly rising current is obtained by the use of the second element. The dashpot shown in the figure will slow down the second element whose function is to tighten the spring restraining the tripping element such that if the current rises slowly a very high value will be necessary to trip the main element. The purpose of using such a relay is to prevent synchronizing currents between the generators, which currents must rise slowly on account of the mechanical inertia of the generators, from causing the relay to operate. A second purpose is to "pre-set" the tripping element as the load upon a section of protected line varies or as the generating capacity connected to the section of line varies.

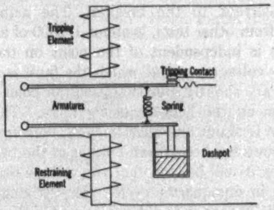

Fig. 4—High-Frequency Pre-Setting Relay-Schematic Diagram

A vacuum tube relay may be substituted very nicely for the mechanical relay, with the advantage of increased speed. A relay used for this purpose is shown in Fig. 5. It is a neon-filled tube with a double purpose; first, to break down at a predetermined voltage in the manner of the well-known glow tube, and second, to pass a high circuit breaker tripping current as a mercury arc rectifier. The two lower electrodes consist of mercury pools, and the upper electrode is a hollow metal cone. If the voltage between the upper electrode and the smaller lower one reaches a given value, a glow discharge occurs between the two, which causes a mercury arc to be formed between the upper and main lower electrodes. The tube is a further development by D. D. Knowles of the earlier Knowles' Grid-Glow Tube. It is capable of momentarily passing a tripping current of a few hundred amperes. The entire action is very rapid.

The connections using the tube relay are shown in Fig. 6. The device at the left takes the place of the pre-setting element on the mechanical relay. The entire relay apparatus in this case operates from voltage, actually the voltage of the current transformer in the line impedance circuit with a high impedance across its secondary. The pre-setting device consists of a one-to-one transformer whose exciting current is obtained from a resonant circuit. The transformer connections are made in such a manner that the secondary voltage, under steady state, opposes the primary voltage and leaves zero voltage across the tube. During the transient, however, as a voltage is applied, the rise of the primary exciting current is very slow, and initially there is a voltage across the tube. Then the tube will operate if the voltage is rapidly increased to the breakdown point, but will not function with a slowly rising voltage.

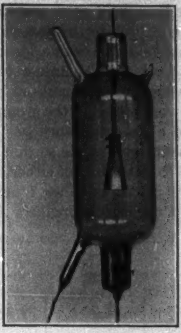

Fig. 5—High-Frequency Vacuum Tube Relay

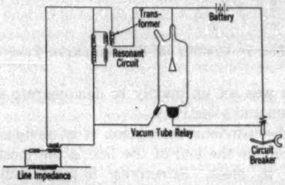

Fig. 6—Circuit Using the Vacuum Tube Relay

Mention has been made of the feature of automatic reclosing of circuit-breakers. If the circuit breakers in Fig. 1 are shunted with a condenser which will pass the high-frequency current only, with the circuit-breaker open, the high-frequency current will retain the relays in their operative position as long as the fault remains on the line. However, at any time that the fault is removed, the relays will return to normal and permit the breaker to reclose. Such a connection would be advantageous if the protected system is liable to faults of short duration.

### RESULTS OF EXPERIMENTAL INVESTIGATION

For the purpose of making an oscillographic study of the system, it was applied experimentally to an 11,000-volt test track contact line at the Westinghouse Works in East Pittsburgh. The experimental circuit is shown in Fig. 7. Four lines were used, and they were joined in pairs at one end in order to give two parallel lines with both terminals at the same location, the latter being for ease in testing. The lines were fed by 11,000-volt single-phase transformer banks at both ends. Two blocking shunts were placed in the grounded side of the transformers and a line-impedance was placed in each line. Arrangements were made so that a short circuit could be applied to either end of either line. Vacuum-tube relays were placed on lines 1 and 4, and were connected to trip the circuit breakers *A* and *B*. The apparatus was set up mainly to demonstrate speed of relay action and selectivity.

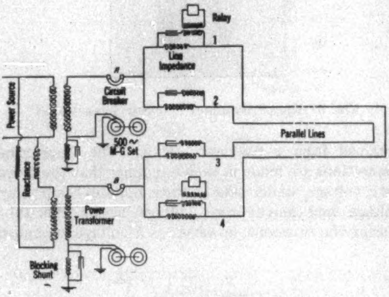

FIG. 7—CIRCUIT OF EXPERIMENTAL TEST

From the previous description it is obvious that a short circuit at the end of the line is the most severe condition to meet. Selectivity is most difficult to obtain, and there is the greatest danger of the auxiliary generators running out of synchronism with the short circuit at this point.

The first tests were made with high-frequency current alone applied to the line. The relays may be properly set, therefore, without the application of power current, by placing short circuits at the various indicated points and adjusting the tube voltage so that it trips with a fault on line (1-4) but not with a fault on line (2-3). The tube relay circuit was that shown in Fig. 6. In making these first tests the low-tension side of the power transformers must be short-circuited.

The frequency used was 525 cycles obtained from a small rotating machine, at 250 volts. Standard oil-filled condensers were used in the impedance circuits; the current transformers also were standard. The oscillogram in Fig. 8 was taken with a short circuit at the end of line 1. The lower element recorded the high-frequency current flowing from line to ground. The other two elements are a record of the current in the upper electrodes of the tube relays at 1 and 4. It will be recalled that both the circuit breaker tripping current (d-c.) and the high-frequency breakdown current flow in this electrode. The film, then, shows the high-frequency current superimposed upon the direct current. The d-c. component is similar to that which flows in the tripping coil of a circuit breaker, and the shape of the curve is familiar. The high-frequency component will be seen to gain in magnitude. The first tube operated two and one-half cycles, high frequency, after the short circuit occurred, and the second tube, two cycles later.

A potential of 11,000 volts was then applied to the lines at a frequency of 25 cycles. A short circuit was placed on line (1-4) at 4, and Fig. 9 is a record of the short-circuit current in line (1-4) at 1 and of the current in the tube relay at the same point. There is no discernible time lag from the instant at which the fault was applied to the instant at which the relay furnished tripping current to the breaker. The actual time, obtained from other tests, is about 1/2000 of a second. This time is independent of the point on the power frequency voltage wave at which the fault is applied, but will vary slightly, depending on the point of fault application on the high-frequency wave. The maximum time is about one-quarter cycle, high frequency. Fig. 10 shows the breakdown voltage of the two tubes, from which it will be seen that the voltage reaches its maximum in one-quarter cycle. The striking feature of the films is that it is not necessary for the relay to wait until the power current becomes excessive before operating. It will be noticed that the speed is much greater with power current on the line, because of the initial charge of the condensers. Fig. 11 shows the short circuit and tube currents with a fault on the line (2-3). Neither tube operated, indicating the perfect selectivity.

### CONCLUSIONS

In principle, super-frequency control has four inherent characteristics which contribute to its value. First, high-frequency currents "know more about reactance" than those of low frequency, which means that the small differences in line reactance which describe the distinction between a fault or normal load may be more easily detected with high frequency. In the second place, by the use of certain high-frequency blocking devices placed in the lines, a network having any degree of complication may be broken up into a number of simple networks at the high-frequency, each of which may be independently measured. This possibility provides a high degree of selectivity between various lines, and independent isolation of faulty conductors without the drawback of time delay.

The third characteristic is that, inherently, high-frequency currents reach their peaks or relay operating values more rapidly than those of normal frequency, thus insuring a high speed of relay operation. Finally, the high-frequency superimposed currents measure the pure impedance of a network, which is not possible with low frequency because of the counter-electromotive force of connected machinery. The advantage of the latter is an independence on the part of the superimposed system of all conditions of loading previous to a fault, an advantage which enhances recognition of fault conditions.

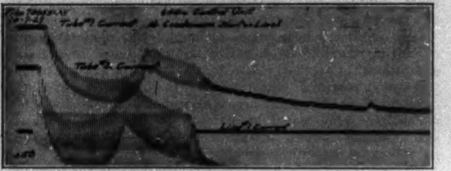

Fig. 8—Oscillogram of Relay Action with High Frequency Alone

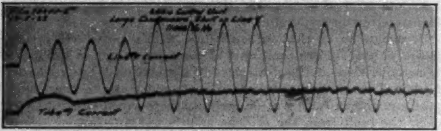

Fig. 9—Oscillogram of Relay Action Under Short Circuit Condition

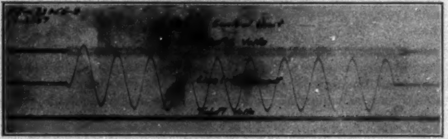

Fig. 10—Oscillogram of Voltage Across Relay During Short Circuit

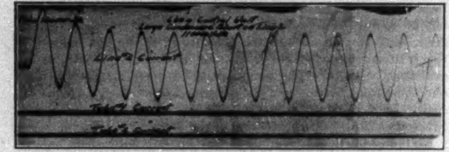

Fig. 11—Oscillogram Showing no Relay Action With Short Circuit on Parallel Line

These inherent advantages lead to many possibilities. In general, the margin by which relays operate or do not operate may be considerably extended. Furthermore, the elimination of many variables in the power circuit by the use of high frequency makes possible accurate and simple calculation of relay operating currents. There are no particularly new principles involved and the system is simple enough to make possible its application to many of the more complex problems in circuit-breaker control.

A great many variations of this super-frequency control are possible, and have entered into experimental work and calculation. The system described has been used in an experimental way only, in order to demonstrate the soundness of its theoretical nature. The results obtained have been interesting and unique, and in themselves predict the future development of a super selective relay equipment.

---

## Discussion

**O. C. Traver:** Mr. Ludwig's paper is very gratifying, not only on account of its definite contents but because of the goal sought. In the hope that it may help in the final solution of the problem, some of the handicaps that must be overcome are mentioned below.

Static and steep wave fronts will probably be very unwelcome on lines equipped with this protection. They might be expected to produce the requisite rate of rise to open the breaker on a perfectly good line.

Higher system voltage and frequency also work their hardships, chiefly from the standpoints of costs of the condensers.

The length of the trial line is not given. It is assumed from the general description to be relatively short. As the length increases the difficulties will multiply. Not only will the line reactance become objectionable, but to hold two 500-cycle generators in synchronism over a 100-mi. line, that is one-fourth cycle apart, would seem difficult. The greatest difficulties are apparent.

The use of the rate-of-rise relay suggests that the 500-cycle generators might sometimes fall out of step. Such condition might be fatal to protection should a fault occur during that interval.

The vacuum-tube relay, on its own account, is a very interesting development. It may not be as accurate as mechanical relays, but its speed will commend it, nevertheless.

**R. G. McCurdy:** As Mr. Ludwig indicates in his paper, telephone engineers are interested in any developments which increase the speed of relay and circuit-breaker operation on power transmission circuits, as such developments tend to minimize the interference which may be caused on adjacent telephone lines, during periods of fault or other abnormal operating conditions.

The schemes discussed by Mr. Ludwig, however, while obtaining a desirable result in improving conditions as regards interference under abnormal power conditions, may cause a considerable increase in noise interference on exposed telephone circuits under normal power-circuit conditions. It seems necessary that in order to make any superimposed high-frequency system function satisfactorily, the magnitude of the superimposed currents must be large as compared to the currents normally present on the power circuit in the same frequency range. It is evident, therefore, that the addition of such control currents employing frequencies in the range used for telephone transmission will increase the telephone interference factor of the power circuit and correspondingly increase the difficulties of coordination with adjacent telephone lines. Assuming 500-cycle voltages of the order of two per cent of the normal frequency voltage, as suggested in Mr. Ludwig's paper, this may result in an increase of the telephone interference factor of the power circuit of the order of 3 to 1.

The efforts which have been carried along for the past few years on the part of the power and telephone companies have been effective in reducing both the influence of the power systems and susceptiveness of the telephone systems. It seems very important that any developments for improving the operation of relay systems which would reduce interference under abnormal power conditions shall be worked out in some way which would not involve at the same time an increase in the influence under normal operating conditions. In the application of high-frequency relaying schemes to power circuits it seems important from the standpoint of inductive coordination that either (1) continuous use of the high frequencies be avoided and their application to the system be confined to the sections of line in trouble and for the period while the trouble persists, or (2) that the control currents, if continuous, shall be at such frequencies and power levels as not to interfere with adjacent communication circuits. It would appear that this latter arrangement must in general mean a considerable reduction of the incidental currents of the power circuits near the frequencies involved.

**D. W. Roper:** I should like to inquire if this system can be used for the protection of lines that are entirely underground. I should also like to inquire how the system could be extended, if at all, so as to cover the most awkward case we have in our system in Chicago.

The most awkward system we have for relay protection is on high-potential transmission lines between generating stations—perhaps I should call them tie lines. The stations are of a capacity of upwards of a hundred thousand kw. apiece. There are transformers at both ends, and the lines are all underground cable. The 12-kv. connecting cable may be a few hundred feet up to two thousand feet from the switch to the transformer. The high-potential transmission line 66 kv. may be something of the order of 10 or 20 mi., and then there is at the other end some 12-kv. cable up to, say, 2000 ft. in length.

There are several systems which apparently work fairly successfully for opening the switches if the fault occurs on the high-potential line. The awkward case is where the fault occurs on one of the 12-kv. lines.

I should like to inquire of the author if it appears feasible to extend the application of his system to this particular case.

**Paul MacGahan:** The first impression obtained from the synopsis, and also from a superficial reading of the paper by Mr. Ludwig, is that in this superimposed high-frequency protection scheme there is a means which would be an improvement upon the present relay practise as regards transmission lines and feeders.

I doubt very much whether the author of the paper had this in mind, because the applications described are apparently upon networks of trolley conductors such as for the more complicated railway electrification systems.

It might be confusing to many, and result in unwarranted or at least premature hopes for further improvements in sectionalizing of feeders and transmission lines, to retain such an impression. While such a development might be possible in the future, it seems to me that the complications, such as, for example, in supplying an unfailing source of high-frequency power, synchronized on each bus, would be very hard to overcome and that, therefore, the proper place for this scheme of relay development is for cases that cannot be handled by means of the present highly accurate overcurrent time-element relays, and directional relays, or impedance relays.

Since the invention by the writer of the well known reverse-power relay, consisting of a sensitive watt element, the contacts of which are in series with the contacts of the overcurrent element, together with the duo-directional contact idea, there have been many mechanical and electrical improvements in the relays themselves and a great experience built up in their proper application, so that now there are few cases which could not be satisfactorily taken care of by the modern relays.

**G. B. Dodds:** In working out the details of construction and application of the relay equipment used, considerable attention should be given to the reliability of this equipment so that its addition to the system will not create an additional hazard.

This applies particularly to the construction of the blocking reactors and the manner of connection to the high-tension lines. In the past, considerable grief has been caused by the failure of choke coils connected in high-tension lines and the possibility of a recurrence of this experience should be carefully avoided.

One question which comes to mind is the method of synchronizing the high-frequency generators located in different substations. Can this be done by the use of the existing power-frequency potential transformers? In connection with the question of synchronizing there is a question in our mind whether a dash-pot relay would be suitable to prevent operation on synchronizing current, as it has been our experience that dash-pot relays are not entirely reliable.

The fact that a protective installation of this type can be tested in the field without actually drawing short-circuit current is greatly in its favor. Several power companies consider field testing of relay installations by actually grounding the lines very much worth while, and this testing would be very much facilitated in an installation of this kind.

It occurs to us that in connection with a protective installation of this nature some sort of back-up protection would be necessary, since if the protective equipment on a line failed to function, or a breaker failed to open and stuck in the closed position while a fault was on the line, there would be nothing to clear the fault from the system, as other high-frequency relays would not obtain sufficient current to operate. Of course this same situation exists in any type of balanced protection and is called to mind here only to point out that the current transformers used for the high-frequency relays should if possible be of such type that overload relays could be used in conjunction with them.

As the author states, a great many variations of high-frequency control are possible and it is to be hoped that among these variations one will be found that embodies simplicity and reliability of equipment and operation along with reasonable cost and maintenance. The scheme described by the author has its possibilities and should be developed.

**D. W. Roper:** I should like to ask the author if his scheme of relay protection is applicable to a case which is found in Chicago and other large cities. This case covers high-tension tie lines between generating stations in which the generators are operating at about 13 kv., 3-phase. Transformers located at each generating station change the pressure from the bus voltage to the transmission voltage which may be from 2 to 5 times the generator voltage. The connections between the transformers and the circuit breakers in the generating stations, as well as the entire high-voltage transmission line are underground, lead-covered cables. The protection of the high-voltage transmission cable is not particularly difficult, but this can not be said regarding the lengths of about 1000 ft. of 13-kv. cable at each end of the line forming the connections between the outdoor transformers and the oil circuit breakers. If a failure occurs on one of these cables at one station, for example, the oil circuit breakers at this station will be opened very promptly by the action of the relays; but if the relays at the other station are set low enough to operate under this condition, then they will also operate and open the line in case of through faults when there is no trouble on this transmission line.

**J. R. Coffin:** (communicated after adjournment) The method which Mr. Ludwig has used for obtaining a source of the high-frequency current (see Fig. 1 of his paper) is to provide at each switching station a small synchronous motor-generator set, the motor being driven from the power frequency of the supply line and the generator operating to produce the high-frequency control potential.

The use of these small motor-generator sets involves certain disadvantages which it is believed could be eliminated by the use of another method of producing the control frequency. These disadvantages are as follows:

1. The problem of proper supervision and maintenance for these numerous small synchronous motor-generator sets would be serious, especially if used as indicated in a-c. railway transformer substations, which ordinarily do not have skilled attendance.

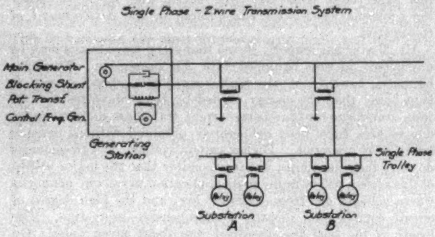

Fig. 1—Application of Central Source of Control Frequency to Single Phase A-c. Railway System

2. The problem of transient interchange of synchronizing power between high-frequency generators at adjacent substations has been covered by Mr. Ludwig in his paper. The presence of these transients requires the introduction of a certain amount of time delay into the relay system which would otherwise be unnecessary.

3. The problem of sustained interchange of synchronizing power between high-frequency generators at adjacent substations is also referred to in Mr. Ludwig's paper. This interchange of power arises because of the phase difference of the power frequency at adjacent substations due to transmission of load along the transmission system, which causes a phase displacement of the motors of the small motor-generator sets. This phase displacement in electrical degrees would be carried over into the high-frequency generators and multiplied by the ratio of the frequencies, so that a relatively small phase displacement in the power frequency would give rise to a much larger displacement in the control frequency. For example, in a railway system operating at 25 cycles a phase displacement of 2 deg. between adjacent substations in the 25-cycle frequency would cause a phase displacement of 40 deg. in the 500-cycle control frequency, which, of course, would result in a relatively large interchange of synchronizing power between the two high-frequency generators. In order to overcome this difficulty Mr. Ludwig has suggested the use of flexible spring couplings in the motor-generator sets. This would permit a reduction of the synchronizing power between adjacent high-frequency generators but it would quite possibly introduce other difficulties due to excessive hunting of the high-frequency generators.

4. Any electrical fault which developed in one of the small motor-generator sets would appear to the relay system as a bus short circuit at the substation and in the absence of special protective devices would result in the isolation of the substation even though no real fault existed on the power system.

The objectionable features just outlined could be avoided and advantages in the way of economy and reduced maintenance could be obtained by substituting a central source of high-frequency potential for the individual motor-generator sets at the substations. Referring to the accompanying Fig. 1, which for the sake of simplicity has been made applicable to a single-phase a-c. railway system, it will be noted that the small motor-generator sets have been eliminated and replaced by a single high-frequency generator located in the main generating plant where presumably it would operate under the most favorable conditions as regards supervision and maintenance. This high-frequency generator introduces into the transmission system a control frequency, the phase position of which at each substation is independent of the load which is being transmitted over the system. This control frequency passes through the ordinary substation transformers and reaches the trolley system without the necessity of any special apparatus at the substation except the small resonant shunts which are used to operate the relays. There is no tendency for a flow of synchronizing power either transient or sustained between the various substations. Should any trouble develop on the control frequency generator in the main generating station, the high-frequency potential would cease, and of course, the system would be left without relay protection until the control frequency was restored. However, the failure of the high-frequency generator would not in itself cause any interruptions or unnecessary circuit-breaker operations. A further advantage accruing from the use of a single high-frequency generator at a central location is the possibility of employing more elaborate apparatus to ensure constant control frequency. As the resonant circuits employed in this system are very sensitive to changes in frequency, difficulty might be experienced due to changes in the power frequency if the two frequencies are mechanically connected through the motor-generator sets.

Fig. 2 herewith, shows the application of the same idea to a d-c. railway system with three different types of a-c.—d-c. substations. The simplest case would be a synchronous-converter substation, as the control frequency would pass directly through the converter and no special apparatus would be required except the relays and resonant shunts. In the case of a rectifier substation there would ordinarily be a reactance choke on the d-c. side of the rectifier which would prevent the passage of the high-frequency control current. In this case the high-frequency control potential could be placed upon the trolley by the use of a potential transformer on the transmission line and a resonant filter circuit applied to the trolley, this resonant filter circuit being designed to pass only the control frequency. An alternate method would be simply to by-pass the reactance choke with a resonant filter circuit, omitting the potential transformer. Resonant shunts for the relays would be required as in the case of the other types of substations. For a motor-generator substation the method of placing the high-frequency control poten-

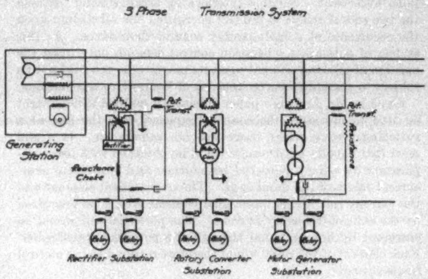

Fig. 2—Application of Central Source of Control Frequency to D-c. Railway System

tial on the trolley system would involve the use of a potential transformer on the transmission system and a blocking shunt in the generator lead. A resistance in the secondary circuit of the potential transformer would also be required. The blocking shunt would then short circuit any frequency which might be present in the transmission system except the control frequency and this control frequency would appear on the trolley system. Resonant shunts in connection with the relays would be required as before.

In Mr. Ludwig's paper it is assumed that the various loads which might be placed upon the transmission system would have relatively low admittance to the control frequency and therefore would not admit a sufficient amount of the control-frequency current to cause difficulty in discriminating between a load and a fault. This assumption seems to be open to question. Assume, for example, that the load is of the order of 10,000 kv-a., and that the source of high-frequency current is of about 10-kv-a. capacity. If the load consists of a transformer and synchronous motor it would have a 25-cycle leakage reactance of perhaps 30 per cent on a 10,000-kv-a. base, which would give a 500-cycle reactance of 600 per cent on a 10,000-kv-a. base, or 0.6 per cent on a 10-kv-a. base, as compared with about 20 per cent in the high-frequency generator itself. The load would of course have no generated counter e. m. f. at 500 cycles. From these figures it seems that the load would appear substantially as a dead short circuit to the control system. This difficulty can be corrected by using a resonant blocking shunt in series with each load.

The use of a blocking shunt on the load suggests the use of a second control frequency for load indicating purposes. For example, in a railway system the locomotive could be equipped with a resonant shunt which would block the relay-control frequency but pass the load-indicating frequency. The load-indicating frequency current could operate a relay which would energize the substation whenever there was a locomotive in the line section on either side and deenergize it when both line sections were clear. Suitable interlocking arrangements between the two sets of relays to prevent energizing the substation upon the occurrence of a fault readily suggest themselves. As this system of automatic substation control depends only upon the position of the load and not upon its magnitude, it would not be subject to complications on account of locomotive regeneration.

Fig. 3 in Mr. Ludwig's paper indicates a method which might be used to introduce the control frequency into the line at a switching station where there was no transformer. It would seem that equally good results could be obtained with less complication by using a potential transformer and directional over-current relays of the usual type. The over-current element and the current coil of the directional element would be energized by the control-frequency current. The potential coil would be energized by line potential through the potential transformer. Each element of the relay would therefore respond to the control frequency only.

**E. A. Hester:** There is one point touched on by Mr. Dodds to which I should like to add a word, and that is the possibility of testing this particular type of protection without actually placing a fault on the system and drawing power current.

In Pittsburgh, we have a network of about the usual complication and we have had a great deal of trouble with grounds. There was a time not so long ago when we tried to predetermine what would happen under various conditions and then set the relay for those conditions. Consequently, many things were overlooked and we had considerable trouble resulting from the operation of the wrong ground relay and often important customers might be shut down.

Finally we decided the only thing to do was to put on actual fault to ground on the line and check the operation of the relays. This is usually done very late at night or at some time of minimum load and by pre-arrangement. Consequently, it is a real hardship on our protection engineer in his organization to get every installation tested. However, within the past two years, we have actually tested most of the installations by putting a ground fault on the line and we have reached a degree of reliability which we once thought we would never be able to reach. I do not mean to say that we have solved the protective problem, but we have found a way to achieve real results with the equipment now available. However, if some means can be found to eliminate the difficulties attending the making of arrangements to make tests at off hours it will be welcomed most heartily and the scheme described by Mr. Ludwig offers real possibilities.

**L. R. Ludwig:** The points brought out in the discussion of this paper have been very well taken, and serve to clarify the problems which were encountered in the development of this system.

Mr. Traver has properly stated that steep wave fronts may be unwelcome on lines equipped with this protection. They are harmless, however, if the high-frequency supplied energy is kept larger than the energy carried by these wave fronts. In tests, transformer-magnetizing-current transients and transients due to arcs, have been deliberately obtained without causing faulty relay operation. Higher system voltages and frequencies do work their hardships, and it is possible that the major utility of this system will be found in its application to railway networks where voltages and frequencies are low, and the high degree of circuit complication dictates comprehensive protection. The length of the trial line described was about seven miles. On such a line it is feasible, and cheaper, to synchronize the generators. For long lines such a procedure would, of course, be impractical, but unnecessary because two or more frequencies may be used with a modified circuit not described in the paper to obviate synchronizing. The rate-of-rise relay has a dual purpose as described, and will prevent relay operation in case the generators are somewhat out of phase, but does not imply that the generators are allowed to fall out of step, which is not the case.

Mr. McCurdy questions the effect on telephone lines of the normal high-frequency currents. Assuming as he does a 500-cycle voltage of two per cent, the telephone interference factor is 30. He has apparently compared this with a factor of 10, which is the best obtainable with pure sine waves. In practise, because of transformer magnetizing currents, etc., systems operate with factors of 20 to 40 regularly. Furthermore, a two per cent voltage is high because the drop in the impedance shunts has been neglected. Also, the telephone interference factor does not tell the entire story, since obviously the ampere-miles of inductive effect cancel out with currents flowing into a section from both ends, and the through-feed currents are necessarily very small because of the impedance shunts. From these facts it is logical to reason that the problem of telephone interference is neither serious nor insurmountable. The problem is further simplified by the fact that the currents are hardly continuous because there are times of light load when practically no high-frequency current will flow. The frequency of 500 cycles, while low on the curve of telephone interference, may not be the best for ultimate use.

Mr. Dodds has raised a necessary question in regard to applying high-frequency apparatus to the lines in such a way that additional hazards are not created. Much depends upon the system to be protected; if it is possible to use small line reactors, they may be connected directly in the line, whereas larger ones would require mounting in a tank of oil equipped with suitable bushings. With regard to synchronizing the generators, this is most easily done by throwing them together regardless of phase position, and letting them pull into step. The dashpot relay has not been used in the form described in the paper, which was diagrammatic, but the relay may gain its time element by electrical means; that is, a mechanical relay may be used in conjunction with the pre-setting transformer shown in Fig. 6. Straight overload relays for back-up protection should be used as pointed out by Mr. Dodds.

Mr. Roper has presented an interesting problem and inquired if a solution is possible by the use of high frequency. So far no tests have been made with cables, and because of their special properties, some difficulties may be encountered. For example, the high-frequency charging current and the effect of the cable capacity will influence the control currents, though there are means of taking these influences into account. So far as the circuit shown is concerned, adequate protection could be secured by properly introducing and blocking the high frequency, but the question regarding cables is at the present time an unanswered one.

Mr. Coffin is correct in stating that there are certain disadvantages in the use of a number of high-frequency generators. This is, however, the most flexible arrangement, and was illustrated because it is applicable to almost any system. In some of the less complicated circuits, numerous simplifications of the system are possible, one of which is shown by Mr. Coffin in his Fig. 1. There is a difficulty in the application shown in this figure, however, which prevents it from being general. Under fault conditions the control current must flow through the high line and transformer, which have considerable impedance. If this impedance is high compared to that of the connected load, it will be impossible to discriminate between load and fault conditions. Blocking shunts in the load circuits could be used as mentioned by Mr. Coffin, but their use was abandoned because of the large expense which they entail due to their being numerous. This point is further clarified by Mr. Coffin's discussion regarding the admittance of loads. The reactance of the load is, in principle, correctly compared to the reactance of the high-frequency generator itself, but reactance in the circuit supplying control current to the lines is disadvantageous in the same way as the leakage reactance of the generator.

In the case of the synchronous-machine load calculated by Mr. Coffin, the figures do not seem complete because the high-frequency and normal-frequency reactances are compared in per cent without taking into account the fact that the voltages at the two frequencies are different. Suppose, for example, that the synchronous motor is supplied from an 11,000-volt line, to which a 250-volt high-frequency generator of 10 kv-a. is connected. The 0.6 per cent reactance of the load as calculated by Mr. Coffin must be multiplied by the ratio of the voltages squared, or the reactance is over 1100 per cent, 53 times that of the generator itself. Calculation using actual ohms impedance yields the same result. In general, the assumption that the load impedance is higher than the line impedance is correct.

The use of high frequency for load-indicating purposes is feasible, and in fact, was one of the first suggested applications of the system described.

The use of a potential transformer for introducing high-frequency currents into protected lines has the objection that the small transformer has too much reactance to permit differentiation between load and fault conditions. A condenser would need to be used with the transformer to neutralize its reactance. Directional relays as suggested, as well as interlocked high- and low-frequency relays, have been used but do not generally seem necessary.

# Extinction of an A-C. Arc

BY J. SLEPIAN[1]

Fellow, A. I. E. E.

***Synopsis.****—The transition from high conductivity to high resistivity which an a-c. arc undergoes on extinction is studied. Theory and approximate calculations are given for the rate of recovery of dielectric strength of the arc space for short arcs, and results are given of experiments on short arcs, and arcs in holes and slots in insulating material and insulating plates. The influence of chemical activity in arc gases is discussed. Factors contributing to the success of the a-c. oil circuit breaker are suggested.*

## 1. INTRODUCTION

THE extinction of an a-c. arc as it is effected in switches and circuit breakers operating in a-c. circuits is fundamentally very different from the extinction of the arc in a d-c. switch. In the latter, by lengthening or otherwise, the arc is brought into such a form that it requires for its maintenance a voltage higher than is generated in the d-c. circuit. The current then decreases, and if the voltage required by the arc remains higher than the generated voltage, the current reduces to zero and the arc is extinguished. In the d-c. switch, then, it is important that the arc voltage be made and kept sufficiently high.

In the a-c. switch, however, the arc while it is playing takes a voltage which is generally smaller than the voltage generated in the circuit, and influences the course of the current only in a minor way. The current following its natural cycle comes to a zero value, and at such a moment, the arc extinguishes. In a very short interval of time embracing this moment of zero current, the medium containing the arc returns from its momentary condition of a comparatively good conductor, carrying current at a low voltage, to its normal condition of a comparatively good insulator supporting the full generated voltage of the circuit with passage of little current. It is this rapid transition at the moment of zero current, from the state of a highly conducting arc to the state of an insulating non-ionized gas which is important for the extinction of the arc in an a-c. switch. This transition must be made sufficiently rapidly if the arc is not to reestablish.

The study of this transition from arc to insulating gas at zero current is therefore not only interesting in itself but is important in that it may reveal principles leading to improvements in a-c. circuit breakers. This paper covers ideas on this subject developed by the author and his co-workers during the past few years.

## 2. TRANSITION TIME AND EXTERNAL CIRCUIT

We shall first consider the question of the time available for the transition from arc to dielectric at the current cycle end in a circuit breaker operating in a practical reactive circuit. It is quite clear that this transition requires a finite time to be effected, that it cannot take place instantly. The conductivity of the medium carrying the arc cannot disappear suddenly. Being due, as we shall assume in this paper, to the presence of ions, time must be given for these ions to disappear, either by neutralizing their charges among themselves by recombination, or by discharging into the electrodes. Now how much time is available for this deionization in a practical circuit?

Consider first the circuit of Fig. 1, consisting of an a-c. generator of large capacity, in series with a reactor and an arc. Assuming that the arc voltage is small compared to the generator voltage, the current will lag by nearly 90 deg., as in Fig. 1C. The voltage across the arc will of course be in phase with the current, as in Fig. 1D. Now if at the end of a half cycle of current, the arc should extinguish and the current remain zero, the voltage across the electrodes would at once rise to the terminal voltage of the generator at that time, and because of the phase relationships this would be the peak of the generated voltage. Hence, in such a circuit, no

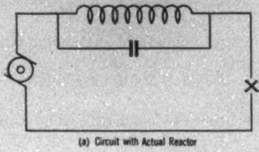
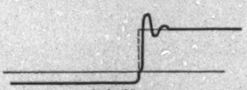
time whatever would be allowed for the arc to lose its conductivity at the end of a current cycle. If the arc extinguished then, the space would immediately have to support the full generated voltage. An arc whose voltage is low relative to the generated voltage could not extinguish in such a circuit.

However, it is only an ideal reactor which could act to produce the results just mentioned. Every actual apparatus must have electrostatic capacity as well as inductance. An actual reactor may be considered as acting as if it were an ideal reactor shunted by a small condenser, as in Fig. 2A. With such a shunted reactor, the voltage across the arc space will not rise instantly after arc extinction to the generator value, but will come on gradually as the reactor undergoes an oscillation. This is shown in Fig. 2B, on a time scale much expanded as compared with Fig. 1. The time for the voltage impressed across the arc terminals to reach generated voltage is one-quarter of the period of a natural oscillation of the reactor. This we may call the time available for the transition from the conducting arc to the insulating gas space.



(a) Circuit with Actual Reactor



(b) Arc Voltage

Fig. 2

This result can evidently be generalized, and we may say that the time available for transition is always as great or greater than a quarter of a period of free oscillation of the circuit external to the arc. In practical power circuits, the frequency of free oscillation may vary from the order of 100,000 cycles per sec. for the case of a current limiting reactor to only a few hundred cycles for the case of a very long transmission line. The time available for the extinction process in the arc, varies then from 2.5 microseconds to several thousand microseconds depending on the character of the external circuit.

It would seem from this that the interrupting capacity of an a-c. switch may under certain conditions be greatly affected by the nature of the circuit in which it operates.

In experimenting on the extinction of a-c. arcs it proved desirable to control the time available for the extinction of the arc. This was readily accomplished by shunting the arc with an adjustable resistance as shown in Fig. 3. In this circuit, immediately after arc extinction the voltage $V$, rises to the generator voltage value following the exponential curve,

$$V = V_0\,(1 - e^{-\frac{R\,t}{L}}) \tag{1}$$

We may take $\frac{L}{R}$, the relaxation time, as the time available for the transition.

The initial rate of rise of voltage impressed upon the arc space as given by equation (1) is

$$\frac{d\,V}{d\,t} = \frac{V_0\,R}{L} \tag{2}$$

The symmetrical short circuit current of the circuit is $I_0 = \frac{V_0}{L\ \omega}$, and the current which flows through the resistor after the arc is extinguished is $I_R = \frac{V_0}{R}$. Hence the initial rate of rise of the impressed voltage is also given by

$$\frac{d\,V}{d\,t} = V_0\,\omega\,\frac{I_0}{I_R} \tag{3}$$

This initial rate of rise of voltage may also be taken as a measure of the time available for the transition, since the arc space must recover dielectric strength at a rate sufficient to withstand impressed voltage growing at the rate given by equation (2) or (3).

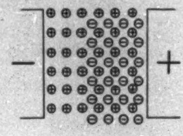
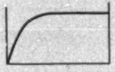
## 3. The Electric Gradient in an Ionized Gas Between Closely Spaced Electrodes

In the last moments of the arc current, and immediately following the current zero, the factors producing new ions have in general ceased their activity, and the ions already in the gas are rapidly diminishing in number by recombination. The rising voltage impressed upon the arc terminals by the external circuit acts therefore upon a gas space containing a diminishing density of ionization. The question then naturally arises as to what is the dielectric strength of an ionized gas as a function of its density of ionization.

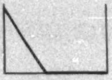
Important in the determination of the dielectric strength is the distribution of the electric gradient in the ionized gas. It is at once clear that the distribution will not be a uniform one. Although, initially, the densities of the positive ions and negative ions may have been everywhere equal, as a result of the application of the electric field this equality is disturbed, and space charges appear which cause the electric field to be distorted. At the cathode negative ions are repelled, and positive ions are attracted. A positive space charge therefore develops in front of the cathode which increases the electric gradient there. Similarly at the anode, a negative space charge and increased gradient also develops.



(a) Distribution of ions in Gas



(b) Potential Distribution in Gas



(c) Gradient Distribution in Gas

Fig. 4

The exact calculation of this gradient distribution is very difficult, although much has been done on this problem by J. J. Thomson, J. S. Townsend, G. Mie, and others.[2] However, we may arrive at a sufficiently good approximation to the gradient distribution for our purposes in the following way. The mobility of the positive ions in the electric field is very small compared to the mobility of the negative ions, which are electrons in the cases in which we are interested. We shall therefore neglect entirely the motion of the positive ions and consider them fixed in space. The negative ions, however, we shall suppose move freely under the influence of the electric field.

With these hypotheses, the effect of the electric field is to move electrons away from the cathode as in Fig. 4, exposing a space charge of positive ions in front of the cathode with charge density, $n\,e$, where $n$ is the number of positive ions per cm.$^3$, and $e$ is the charge of an ion. This space charge causes a considerable portion of the impressed voltage to be consumed in the region next to the cathode. The thickness of the space charge will grow until all the impressed voltage is consumed in the cathode space. Assuming now that the diameter of the section of the ionized gas is large compared to the distance between the electrodes, we may apply Poisson's equation for one dimension and taking $e = 4.77 \times 10^{-10}$ e. s. u. we readily arrive at the following relations.

Thickness of space charge, $d$,

$$d = 1.05 \times 10^3 \sqrt{V/n} \tag{4}$$

Gradient in space charge at distance $x$ from cathode,

$$\frac{d\,V}{d\,x} = 1.8 \times 10^{-6}\, n\,(d - x) \tag{5}$$

Maximum gradient in space charge

$$\left(\frac{d\,V}{d\,x}\right)_{max} = 1.89 \times 10^{-3} \sqrt{V\,n} \tag{6}$$

Mean gradient in space charge

$$\left(\frac{d\,V}{d\,x}\right)_{mean} = 0.95 \times 10^{-3} \sqrt{V\,n} \tag{7}$$

These equations will apply of course only if the thickness of the cathode space charge as given by equation (4) is less than the distance between the electrodes.

## 4. First Approximation to the Dielectric Strength of an Ionized Gas Between Closely Spaced Electrodes

As a first approximation we may assume that electrical breakdown of the ionized gas will occur if the maximum electric gradient in it exceeds a certain critical value. For the sake of definiteness let us take for this critical value, a value approximately appropriate for air at normal pressure and temperature, namely 30,000 volts per cm. From equation (6) then it follows that breakdown will occur when

$$\left(\frac{\partial V}{\partial x}\right)_{max} = 1.89 \times 10^{-3} \sqrt{V\,n} = 30{,}000 \tag{8}$$

or

$$V = 2.52 \times 10^{14} \times \frac{1}{n} \tag{9}$$

The breakdown voltage then varies inversely as the density of ionization, and is independent of the distance between the electrodes, so long as the electrode separation is greater than $d$, given by equation (4).

If the gas is at temperature $T$, we may assume, still as a first approximation, that the critical gradient varies inversely as the absolute temperature. Equation (9) then becomes

$$V = 2.52 \times 10^{14} \times \left(\frac{273}{T + 273}\right)^2 \times \frac{1}{n} \tag{10}$$

---

[2] *Handbuch d. Physik*, by Geiger and Scheel (published by Springer), Bd. XIV, page 6.

## 5. THE DECAY OF IONIZATION IN A GAS

During the transition period immediately after the current zero, the dielectric strength of the arc space is rapidly increasing due to the decrease in the density of ionization, as given by equations (**9**) and (**10**). For an arc in the open, the ionization disappears principally by recombination. The rate of loss of ions by recombination is given by

$$-\frac{d\,n}{d\,t} = \alpha\, n^2 \tag{11}$$

where $\alpha$ is the coefficient of recombination.* The solution of this equation is

$$\frac{1}{n} - \frac{1}{n_0} = \alpha\, t \tag{12}$$

where $n_0$ is the density of ions at time $t = 0$. Where $n_0$ is very large, as in the case of the arc which we are considering, $\frac{1}{n_0}$ is negligible, and (**12**) becomes

$$n = \frac{1}{\alpha\, t} \tag{13}$$

The numerical value to take for $\alpha$ in this equation is rather uncertain. For air at normal pressure and temperature several investigators have found $\alpha = 1.3 \times 10^{-6}$ for "aged" ions. Plimpton[3] found values for $\alpha$ for ions aged 0.05 sec. and longer, and an extrapolation of his values for age zero would give $\alpha$ equal to about $7.6 \times 10^{-6}$. As for the influence of temperature at constant pressure, Phillips[4] has found the following variation in relative values at different temperatures.

| Absolute Temperature | 289 | 373 | 428 | 449 | 546 |
|---|---|---|---|---|---|
| $\alpha$ | 1.0 | 0.5 | 0.399 | 0.360 | 0.178 |

For our purposes, probably the best we can do is to take $\alpha$ inversely proportional to the cube of the absolute temperature.

## 6. THE RECOVERY OF DIELECTRIC STRENGTH IN THE TRANSITION FROM AN ARC. FIRST APPROXIMATION, SHORT ARC

Combining the results of sections 5 and 6, we get from equations (**9**) and (**13**) taking $\alpha = 7.6 \times 10^{-6}$

$$V = 1.9 \times 10^9\, t \tag{14}$$

If we take into account the influence of temperature assuming $\alpha$ varies as the inverse cube of the temperature, and that the breakdown gradient varies inversely as the temperature we get

$$V = 1.9 \times 10^9 \times \left(\frac{273}{T + 273}\right)^5 \times t \tag{15}$$

Even allowing for the uncertainty of the numerical constants, these equations show that the recovery in dielectric strength is very rapid. In ten microseconds, if the gas is cold, the arc space is capable of withstanding several thousand volts. According to these equations a low voltage a-c. arc should extinguish in a circuit such that during the transition time the rate of increase of voltage applied to the electrodes is less than between $10^6$ and $10^8$ volts per sec.

Aside from the uncertainty of the constants used in the preceding development, the nature of the departures from the physical facts made in deriving this approximate theory should be borne in mind. First, it was assumed that the positive ions have zero mobility, and that the positive ion density in the cathode space charge is the same as that in the body of the gas. Actually, these assumptions are not true, and an attempt is made in the Appendix to take the mobility of the positive ions into account.

Second, it was assumed that there exists a critical breakdown electrical gradient for air, such that if this gradient is exceeded at any point, the gas will break down. Actually, however, although for larger electrode spacings for a given pressure, the mean gradient at breakdown is nearly constant, for short spacings the gradient at breakdown increases very rapidly as the spacing is decreased. In fact, as is well known, there is a minimum voltage which will produce breakdown regardless of electrode spacing, and for air this minimum voltage is about 300 volts. Account of this factor will be taken in a later section.

Third, it was assumed that the linear dimensions of the section of the ionized gas was large compared to the thickness of the cathode space charge. This will fail to be the case when very small alternating currents are considered or when the arc is confined to small holes or narrow slots, as will be shown in section 12.

## 7. EXPERIMENTS ON THE EXTINCTION OF A SHORT A-C. ARC IN THE OPEN

Some time ago Mr. L. R. Golladay and the author made a study of the interrupting capacity of the multigap lightning arrester. This arrester consists of knurled brass cylinders spaced one-sixteenth of an inch apart, and some of the gaps so formed are shunted by resistors.

Tests on individual gaps were made in a circuit like that of Fig. 3. The arc was started by a small fuse wire, and the shunting resistor $R$ was varied. For sufficiently low values of $R$ the arc would extinguish at the end of the half cycle, but for large values of $R$, the arc would persist. The limiting value of $R$ which would cause the arc to extinguish was determined for currents varying from 100 to 500 amperes, and voltages varying from 300 to 600 r. m. s. Tests were made both at 25 cycles and 60 cycles.

It was found that the limiting resistance varied inversely as the arc current, inversely as the frequency, and was approximately independent of the voltage.

[4] Phillips, *Proc. Roy. Soc.*, London (A) V. 83, 1910, p. 246.

These results applied to equation (**3**) show that $V_0 \omega \frac{I_0}{I_r}$ was constant or that $\frac{d V}{d t}$ was constant. Thus the arc would extinguish if during transition the rate of increase of applied voltage was less than a critical value, and would persist if the rate of increase of applied voltage was greater than this value. This critical value was found to be $25 \times 10^6$ volts per sec.

It is interesting to compare this result with equation (**15**). A reasonable value to take for the temperature in the neighborhood of the cathode would seem to be the boiling point of brass or about 1200 deg. cent. Substituting in (**15**) we get $\frac{d V}{d t} = 0.4 \times 10^6$. If we take the melting point, or 940 deg. cent. we get $\frac{d V}{d t} = 1.1 \times 10^6$. These values are rather small compared to $25 \times 10^6$ but agree better with the results obtained in section 11, so that in these experiments perhaps a large part of the discrepancy is due to differences between the properties of zinc vapor and air, as the arc extinction probably took place in zinc vapor.

## 8. Chemical After-Effects in Gases from an Arc

The rapidity of recovery of dielectric strength of the arc space predicted by the preceding theory and confirmed by the experiments described in section 7, would seem to be contradictory with experience, as it is well known that gases coming from switch arcs frequently cause flashover of live parts, hundredths or tenths of a second after the gases have left the arc. However, it appears that it is a chemical activity in these gases because of their composition, which is responsible for their continuing low dielectric strength rather than the fact that they originated in an arc. Thus, in the copper arc, large volumes of copper vapor may be given off at the electrodes. This vapor will burn in air forming a flame. Since the burning as a flame involves the diffusion of oxygen of the air into the copper vapor, and since this is a relatively slow process, the burning of the flame may continue for a considerable time. Such balls of flame are frequently seen rising in the air after the extinction of the arc, when high speed pictures are taken of a copper arc, as for example in a commutator flashover. These flames have a low dielectric strength as long as they are burning. When arcs exist under conditions where little vapor or combustible gas is given off practically no persisting flame is observed after the arc is extinguished.

The substantiation of the above statements lies in studies made by J. E. McGee and L. Dennault, not as yet published.

## 9. Arcs Through Holes in Metal Plates

From the theory so far given, and accepting the experimental value of $25.10^6$ volts per sec. as the rate of recovery of dielectric strength of the arc space, it would seem that an arc in the open air is not a practical means for interrupting a-c. circuits of voltages higher than a few hundred volts. For example in a 2300-volt r. m. s. circuit, the arc space would require $1.3 \times 10^{-4}$ sec. to recover sufficient dielectric strength to withstand the peak voltage of 3250. Practical circuits in general will be faster than this, so that the arc will not extinguish. It is possible, of course, to slow down the rate of rise of the voltage applied to the arc terminals during the transition period by shunt resistors, and equation (**3**) shows that for 60-cycle current the resistors after the arc is interrupted need to carry only five per cent of the current interrupted. Nevertheless, even with this low ratio of resistor current to current interrupted, the resistors become very large and expensive for a high power switch, and for higher voltages the resistor current ratio rises proportionally so that matters become much worse.

It occurred to the author that conditions might be considerably improved if the arc was caused to play through small holes or openings in metal plates. In this way ions could disappear by discharging into the metal plates during the transition time, instead of having to depend only on the recombination in the gas space, and so the deionization would be greatly accelerated. Space charges would be produced in the neighborhood of each plate which would consume some of the impressed voltage so that each perforated plate would to a certain extent, act like a cathode as described in section 3. By having a number of these perforated plates in series, the rate of recovery of dielectric strength would be multiplied proportionally. It was believed, and subsequently substantiated that the arc could play through the perforations of the plates for several half cycles (60-cycle current) without melting the metal, whereas it was believed that the arc terminals were necessarily molten.

Many tests of these ideas were made by J. H. Neher and others. In one, as an example, nine sheets of 16-in. brass gauze, made of 0.032 in. diameter wire, were stacked parallel to each other between two solid copper plates, the sheets being separated by 1/16 in. insulating spacers. An arc of several hundred amperes drawn in a reactor circuit of 2200 volts 60 cycles was then blown into the structure by an air blast, the arc terminals being on the solid end plates and the arc stream playing through the holes in the gauze. Resistance in shunt was varied to determine the limiting value which would cause the arc to extinguish at the end of its first half cycle in the structure. In this way, it was found that the rate of recovery of dielectric strength in the structure was $80 \times 10^6$ volts per sec. or more than three times as fast as for an arc in the open. By using appropriate shunting resistors, current up to 1600 amperes at 6600 volts was interrupted by the structure.

Tests were also made on the rate of deionization occurring when the arc was confined to circular holes of various diameters in plates of various thicknesses. Nine plates, each with a hole and two end plates, were stacked together with insulating separators 1/16 in. thick. The end plates were provided with very fine holes just large enough to pass a fine copper fuse wire. All the holes were lined up, and the copper fuse wire threaded through, and an arc started by short circuiting a small 2200-volt, 60-cycle generator, giving 200-amperes short circuit current, upon the fuse wire. Oscillograms were taken, and resistance in shunt to the fuse was varied so that it would just cause the arc to extinguish at the end of the first half cycle of current. From the oscillograms the rate of change of current, $\frac{dI}{dt}$ at the end of each half cycle was measured, and the initial rate of rise of applied voltage at transition was taken to be $R \frac{dI}{dt}$ where $R$ was the value of the shunting resistance.

The results are given in the curves of Fig. 5. The right hand boundary of each shaded region gives the largest rate of rise of applied voltage observed at which the arc did not restrike, and the left hand boundary gives the smallest rate of rise of applied voltage observed at which the arc did restrike.

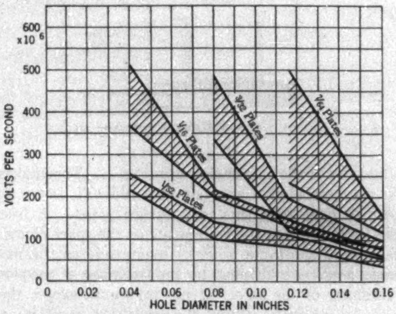

Fig. 5—Arc in Holes in Metal Plates

As was to be expected, the smaller the diameter of the hole, the greater was the rate of recovery of dielectric strength, and for the small holes, values greater than 350 × $10^6$ volts per sec. were obtained. This is 35 × $10^6$ per sec. per plate, and seems to contradict the results of Golladay and Slepian mentioned in section 8, where 25 × $10^6$ volts per sec. was found as the limiting value for a solid cathode. It was hardly to be expected that the perforated plates would act as well as solid plates.

The explanation is to be found in the low voltage per plate, less than 220 volts r. m. s. used in these tests as will be explained in the next section.

## 10. Recovery of Dielectric Strength of Short Arcs at Low Voltages

Equations (**14**) and (**15**) developed for an arc in the open, with solid cathode show that the arc space recovers dielectric strength at a constant rate immediately after extinction of the arc. Experiments at 300 to 600 volts r. m. s. with brass electrodes described in section 7, indicated that this rate of recovery was about 25 × $10^6$ volts per sec. In deriving the equations (**14**) and (**15**) it was assumed that there was a definite critical electric gradient which if it was exceeded at any point, would cause breakdown and restriking of the arc. However, it is well known that the mean gradient at breakdown of short spark-gaps increases rapidly as the length of the gap decreases, and that even for very short gaps, breakdown does not occur with less than a certain minimum value of voltage. For air, this minimum breakdown voltage is about 300 volts, or about 215 volts r. m. s.

It might be expected then, that as the arc circuit voltage is reduced down towards the value 215 volts, r. m. s., the mean rate of recovery of dielectric strength will increase very rapidly, and that for voltages below 215 volts r. m. s., it will be of a different order of magnitude than for voltages much above 215 volts r. m. s.

The same conclusion may also be reached by way of the current ideas concerning the difference in mechanism of a glow discharge and an arc discharge. In the glow discharge, it is believed that all the ionization is due to collisions of ions caused to move with sufficient velocity by high electric gradients. In the arc, it is believed that other factors produce ionization, such as high temperatures, or direct action of $10^6$ volt/cm. gradients upon the cathode, etc.[5] At the time the current passes through zero these other factors have ceased their activity. If the discharge is to restrike, it must restart as a glow. But the glow discharge requires for its maintenance a certain minimum voltage, the normal cathode drop, and this normal cathode drop is very nearly equal to the minimum sparking potential of the gas.

Thus, we again conclude that the first few hundred volts of dielectric strength are recovered almost instantly as compared with the recovery of the later increments of dielectric strength.

## 11. Experiments on Recovery of Dielectric Strength of Short Arcs at Low Voltages

The conclusions of the preceding section found confirmation in the following experiment. Sheets of copper were stacked together with 1/16 in. separators, and an arc of several thousand amperes in a circuit of adjustable voltage from 2300 volts down, was blown into the structure, thus causing a series of short arcs to be produced between successive sheets. A suitably disposed magnetic field then caused these arcs to move in an annular path, and the arcs retraced this path so rapidly that practically no melting or burning of the metal sheets resulted. Details as to the construction of these sheets and the magnetic field will be given in a later paper. As a result of the lack of melting of the sheets there was no flame of burning copper vapor to complicate the results as described in section 8, and it is probably correct to say that the arc extinction took place in air rather than in copper vapor.

---

[5] K. T. Compton, Trans. A. I. E. E., Vol. XLVI, 1927, p. 868.

The number of copper sheets was varied, also the circuit voltage and the value of shunt resistance which would just cause the arcs to extinguish at the first current zero was determined. From these values of shunt resistance, the rate of rise of applied voltage was calculated by equation (3) and the curve of Fig. 6 was obtained.

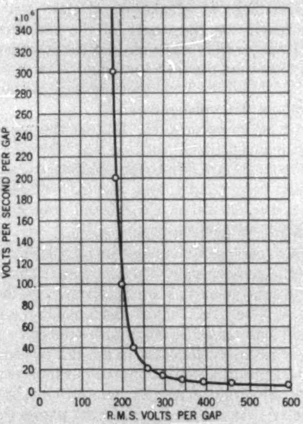

Fig. 6—Recovery of Dielectric Strength of Short Arcs in Air

For voltages per gap above 500 r. m. s. the mean rate of recovery of dielectric strength was $4 \times 10^6$ volts per sec. This seems to be very low compared to $25 \times 10^6$ volts per sec. observed by Golladay and Slepian for brass electrodes, but agrees better with the value calculated in section 7 thus indicating that air deionizes more slowly than zinc vapor. As the voltage per gap was reduced, the rate of recovery of dielectric strength increased reaching $300 \times 10^6$ volts per sec. at 180 volts per gap. For lower voltages per gap than this the rate of recovery could not be determined, as the arc would extinguish even when the shunting resistor was omitted.

The curve of Fig. 6 appears to have an asymptote at 165 volts r. m. s. corresponding to a peak of 235 volts. The normal cathode drop for copper in air is 252 volts.[6] Thus the conclusions of the preceding section are confirmed.

## 12. Long Arcs and Arcs in Slots and Holes in Insulating Materials

Equations (**14**) and (**15**) state that the rate of recovery of dielectric strength of the arc space measured in total volts applied per second is a constant. In deriving this relationship, it was assumed however that the linear dimensions of the cross-section of the arc space were large compared with the distance between the electrodes. This is certainly not the case for long arcs, or for arcs compelled to play in small holes or slots in insulating material.

When the space charge region before the cathode is long compared with the linear dimensions of its section, Poisson's equation in one dimension cannot be applied, and it is no longer true that the maximum electric gradient, at the cathode, is a function only of the total applied voltage as is given in equation (**8**). The boundary of the space charge region is no longer a plane parallel to the cathode surface, but it tends to run up on the sides of the hole or slot as in Fig. 7. This makes even an approximate analysis very difficult, but it is hoped to deal with this in a future paper. A first study indicates that the voltage across the space charge sheath is of the same order of magnitude as the impressed *gradient* multiplied by the thickness of the slot or diameter of the hole. Hence we would expect the arc to extinguish if during the transition there is an almost instantaneous application of a *gradient* of the order of two or three hundred volts divided by the hole diameter or slot width.

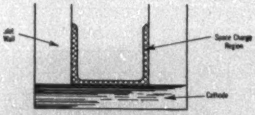

Fig. 7—Space Charge Region for Arc in Slot

The curve of Fig. 8 obtained by Mr. R. C. Mason for slots and holes in soapstone one to two inches long roughly bear out this conclusion. The gradients given are those at which the unshunted arc would just extinguish at the end of the first half cycle. If we multiply this gradient by the width of slot we get for the different slot widths the following:

1/16 in. slot, 143 volts
2/16 in. slot, 146 volts
3/16 in. slot, 92 volts
4/16 in. slot, 63 volts

These are all at least of the right order of magnitude. Mr. Mason's results show that in narrow slot arcs can be interrupted in circuits of very considerably higher voltage than in the open air.

## 13. THE OIL CIRCUIT BREAKER

The success of the oil circuit breaker in high power a-c. systems is probably due in part to all the factors discussed in the previous sections. Most important of all undoubtedly is the fact that the arc under oil is in an oxygen free atmosphere. Hence, in spite of the fact that quantities of hydro-carbon gases are produced by the decomposition of the oil, due to the lack of oxygen no persistent combustion flame follows the extinction of the arc at zero current.

The confining action of oil upon the arc raises enormously the impressed gradient at which the current can be interrupted, just as the narrow slots did as described in section 12. The arc plays in a hydrocarbon gas "hole" through the oil, and at the time the current is passing through zero this "hole" may be of relatively small section.

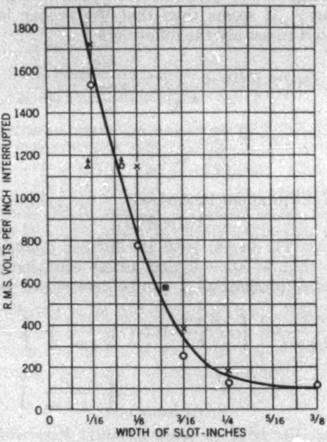

FIG. 8—EXTINCTION OF ARC IN SLOT

Another factor which is very likely of considerable importance is the electrical conductivity of the hot oil immediately adjacent to the arc, and which probably contains decomposition products. The conductivity of this oil may be very large just at the moment the arc extinguishes, although of course, it would fall off very rapidly as the hot oil mixes with the cold oil about it. No information is available as to the magnitude of this conductivity but it seems very probable that it is sufficient to influence appreciably the rate of rise of applied voltage during the extinction process, as considered in section 2.

Still another possible factor is the influence during the extinction period of drops of oil or the carbonized residues of drops of oil floating in the arc space. These particles will form centers for the ions to discharge upon, very much as the wires of the gauze sheets in the experiment of section 9. Space charges will form in the neighborhoods of these particles which will tend to relieve the region immediately adjacent to the cathode from the high gradient which it would otherwise have.

## 14. SUMMARY

The time interval allowed by the external circuit for the arc space to recover its insulating properties after a current zero, is important in the operation of an alternating switch. The low dielectric strength of an ionized gas is to be attributed to the non-uniform potential gradient caused by the development of space charges. Calculations with certain approximations lead to the conclusion that in the case of arcs which are short in comparison with the diameter of their section, the first one or two hundred volts of dielectric strength are recovered almost instantly while later increments of dielectric strength are recovered at a rate lying between one million and one hundred million volts per second. Experiments have been carried out substantiating this conclusion.

For an arc which is long with respect to the diameter of its section the manner of recovery of its dielectric strength is not so simply stated. It is probably nearly correct to say that the ability to withstand a certain electric gradient is recovered almost instantly, and that later increments of dielectric strength return more slowly. The magnitude of this gradient varies in an inverse manner with the linear dimensions of the section of the arc as shown by experiments of Mason.

Experiments of Neher and others have shown the possibility of increasing the rate of recovery of dielectric strength by causing the arc to pass through holes in metal plates or the openings in metal gauze sheets.

A continuing chemical activity in the gases from an arc may cause the persistence of low dielectric strength for times long in comparison to those predicted by the preceding theories.

The success of the a-c. oil circuit breaker is to be attributed to all the factors considered in this paper.

## 15. ACKNOWLEDGMENT

This paper gives an account of general ideas and principles developed on the extinction of a-c. arcs by a considerable number of men working with the author for the past few years. Many of the topics touched upon are of great interest in themselves, and it is hoped that they will be elaborated upon in later papers by the men who have carried on the work. Besides the men already mentioned in the paper, those who have contributed largely to the topics discussed are B. P. Baker, R. C. Dickinson, G. H. Cole, and F. C. Todd, but first and foremost should be mentioned A. C. Crago, who in spite of his untimely death in 1925, continued to influence the work through the wealth of ideas and inspiration he left behind him.

## Appendix

### MATHEMATICAL TREATMENT OF EXTINCTION OF AN ARC MOBILITY OF POSITIVE IONS CONSIDERED

The arc space will be considered as consisting of two sharply defined regions, as in Fig. 4. One, next to the cathode contains only positive ions. The other, the rest of the gas space, contains positive and negative ions in equal numbers.

Let $l$ = thickness of cathode region at time $t$.
$i$ = current density at time $t$.
$V$ = potential at point distant $x$ from cathode at time $t$.
$X = -\dfrac{\partial V}{\partial x}$
$v$ = velocity of positive ions toward cathode at point $x$.
$k$ = mobility of positive ion.
$e$ = electronic charge.
$n$ = density of positive ions in cathode region at point $x$.
$n_0$ = density of positive ions in body of gas at time $t$.
$n_{00}$ = initial density of positive ions.
$\alpha$ = coefficient of recombination of ions.
$B$ = rate of increase of impressed voltage.
$V_0 = B\,t$ = potential impressed on electrodes.

In the cathode region we have the following relations:

$$i = n\,e\,v \qquad (1)$$

$$v = k\,X = -k\frac{\partial V}{\partial x} \qquad (2)$$

$$\frac{\partial^2 V}{\partial x^2} = -4\,\pi\,n\,e \qquad (3)$$

the displacement current, $\dfrac{1}{4\,\pi}\;\dfrac{\partial X}{\partial t}$ being neglected.

Eliminating $n$ and $v$ from these equations and integrating,

$$\frac{\partial V}{\partial x} = \sqrt{-\frac{8\,\pi}{k}\,i\,x + A} \qquad (4)$$

where $A$ is a constant of integration. Substituting (4) in (3) we get

$$n = \frac{i/e}{k\sqrt{-\dfrac{8\,\pi\,i}{k}\,x + A}} \qquad (5)$$

In the main body of the gas we have

$$\frac{d\,n_0}{d\,t} = -\alpha\,n_0^2 \qquad (6)$$

Integrating this gives

$$\frac{1}{n_0} = \frac{1}{n_{00}} + \alpha\,t \qquad (7)$$

If $n_{00}$ is very large (7) becomes

$$n_0 = \frac{1}{\alpha\,t} \qquad (8)$$

The neglecting of the displacement current in equation (**1**) is probably justified except near the boundary of the space charge region adjacent to the body of the gas. Here, we have space charge constantly being freshly exposed by the motion of the space charge boundary, and the conduction current is correspondingly reduced. In the main body of the gas, however, the displacement current is again zero, and the conduction current is the total current, and not very different from the conduction current in the space charge region away from the space charge region boundary. It seems then that the proper boundary conditions to use are the following:

$$n_0 = n\,(l) = \frac{i/e}{k\sqrt{-\dfrac{8\,\pi\,i}{k}\,l + A}} \qquad (9)$$

$$\frac{d\,l}{d\,t} = \frac{i}{n_0\,e} \qquad (10)$$

Last, if the gradient in the body of the gas is negligible,

$$V_0 = V\,(l) \qquad (11)$$

Applying (**11**) to (**4**) with the further boundary conditions that $V\,(0) = 0$ and using equation (**9**), the constant of integration $A$ can be determined leading to

$$V_0 = \frac{k}{12\,\pi\,i}\left\{\left[\frac{8\,\pi\,i}{k}\,l + \left(\frac{i}{k\,e\,n_0}\right)^2\right]^{3/2} - \left[\frac{i}{k\,e\,n_0}\right]^3\right\} \qquad (12)$$

(**12**) together with (**8**) and (**10**) and $V_0 = B\,t$ form a complete system of equations for determining $l$, $n_0$, and $i$. The solution is

$$l = \frac{\sqrt{B}}{\left[\dfrac{\alpha}{12\,\pi\,k^2\,e}\left(\left[1 + \dfrac{8\,\pi\,k\,e}{\alpha}\right]^{3/2} - 1\right)\right]^{1/2}}\,t$$

$$i = \frac{\sqrt{B}}{\left[\dfrac{\alpha^3}{12\,\pi\,k^2\,e^3}\left(\left[1 + \dfrac{8\,\pi\,k\,e}{\alpha}\right]^{3/2} - 1\right)\right]^{1/2}}\,\frac{1}{t} \qquad (13)$$

$$V_0 = B\,t$$

The maximum gradient, $\dfrac{\partial V}{\partial x}$, which occurs at $x = 0$ is given by

$$\left(\frac{\partial V}{\partial x}\right)_0 = \left(\frac{12\,\pi\,e}{\alpha}\;\frac{1 + \dfrac{8\,\pi\,k\,e}{\alpha}}{\left[1 + \dfrac{8\,\pi\,k\,e}{\alpha}\right]^{3/2} - 1}\right)^{1/2}\sqrt{B} \qquad (14)$$

If we assume as in sections 4, 5, and 6 that there is a definite critical breakdown gradient $G$ for the gas, we have for the rate of recovery of dielectric strength,

$$B = \frac{\alpha^2}{144\,\pi^2\,e^2}\left(\left[1 + \frac{8\,\pi\,k\,e}{\alpha}\right]^{1/2} - \left[1 + \frac{8\,\pi\,k\,e}{\alpha}\right]^{-1}\right)G^2 \qquad (\mathbf{15})$$

Changing to practical units we have for $B$ and $G$ in volts per cm., and $k$ in cm./sec. per volt/cm., and letting $e = 4.77 \times 10^{-10}$ e. s. u.

$$B = 1.02 \times 10^{13}\,\alpha^2\left(\left[1 + 3.59 \times 10^{-6}\,\frac{k}{\alpha}\right]^{1/2} - \left[1 + 3.59 \times 10^{-6}\,\frac{k}{\alpha}\right]^{-1}\right)G^2 \qquad (\mathbf{16})$$

Substituting in numerical values we may take for air at normal pressure and temperature, $\alpha = 7.6 \times 10^{-6}$ (from section 5) $k = 1.4$[7], and $G = 30{,}000$. This gives $B = 3650 \times 10^6$ volts/second.

At 940 deg. (as in section 5) taking $\alpha$ as varying inversely as the cube, and $G$ inversely as the first power of the temperature we have $\alpha = 1.06 \times 10^{-7}$, and $G = 7100$. As for $k$, according to Phillips,[8] and Kovarik,[9] the variation will be as the first power of the temperature and so at 940 deg., $k = 6.2$. With these values (**16**) gives $B = 81 \times 10^6$ volts per sec.

At 1200 deg. we have $\alpha = 4.8 \times 10^{-8}$, $G = 5600$, and $k = 7.5$ giving $B = 15.6 \times 10^6$ volts per sec.

## Discussion

**R. W. Sorensen:** These figures given in Fig. 1, which are primarily theoretical figures, to show what happens across an arc, have been checked by us in the laboratory and we get figures of the same form.

Under oil the voltage across the arc is around 150 to 250 volts on an ordinary 200,000-volt breaker. The voltage across an arc in rather high vacuum is only of the order of about 12 to 13 volts, occasionally as high as 20 volts. The amount of energy to be accounted for can be measured by these voltages encountered and shows quite a difference, one being approximately ten times the other.

A phenomenon of interest shown by some oscillograms I have seen may make some other modifications of some of the work here. Under some conditions the current goes out before it crosses the zero line. In other words, you don't have to get down always to zero current apparently to have the arc go out.

That introduces another phase. If the long arc gradients could be eliminated by reducing all the arcs to short ones, this would not only tremendously simplify the theoretical problem, as Dr. Slepian has pointed out, but would also simplify actual operation. The work which he has suggested, which he and his associates are doing, in getting around these long arc gradients by means of holes through metals, et cetera, certainly will be of great value to us.

**R. M. Spurck:** Mr. Slepian's paper brings out a number of points as characteristics of the a-c. arc that have been recognized and studied by all circuit breaker designers for a number of years.

Two points impressed me. (1) The rate of voltage increase of the arc voltage after the voltage or current has passed through zero is one of the factors tending to cause a reestablishment of the arc. This rate of voltage reestablishment varies widely in different systems. (2) The tendency to reestablish the arc may be reduced by artificial means.

From an oil-circuit-breaker standpoint this means that if the tendency of the arc to reestablish is reduced a shorter arc length is obtained. This shortening of the arc length reduces the amount of gas formation in the breaker during its operation and the reduction in the amount of gas formation results in a reduction in duty on the breaker.

Consider first the rate of the rise of the reestablishment of the arc voltage. Inasmuch as it is dependent on the system and generator characteristics it is not, in general, usually practical to lighten the duty on the breaker by changing the system or generator characteristics. Neither is it possible from a practical standpoint to analyze a system and determine the rate of voltage reestablishment so that a breaker of light duty can be put on some systems and a heavier breaker put on systems having more severe duty.

It is, therefore, necessary to design an oil circuit breaker so that it will operate under the worst conditions of reestablishing voltage that any practical system can produce. The effect of reestablishing voltage also serves to explain why oil circuit breakers perform well in some locations and not so well in others.

Consider next the question of artificially reducing the effect of the reestablishing voltage on prolonging the arc. One of the artificial means suggested by Mr. Slepian was the use of shunt resistors across the circuit-breaker terminals. This he discards as impractical from a regular operation standpoint, and I quite agree with him.

Another way of artificially reducing the effect of the reestablishing voltage or the arc length under definite conditions of arc-voltage reestablishment is to increase the insulation strength of the arc stream by cooling or by pressure. In practise this has been done for a number of years by the use of the explosion chamber which utilizes the gas formation from the arc to increase the pressure around the arc stream and to blast cool oil through the arc stream. The efficacy of this device has been proved by many tests and wide experience.

**C. D. Ainsworth:** With the advent of high-potential alternating current came the oil circuit breaker. The principles of the earlier air-break circuit breaker designed for the older d-c. circuits crept into or influenced the design of this new device to such an extent that even today we are confronted with recommendations and demands for mechanical speed of break that involve us in designs that must expose to a high-power, high-voltage arc vast areas of oil. There must result, in addition to the destructive pressures during each succeeding cycle of arc, the excessive volumes of hydrocarbon gas which produce those pressures,—volumes of gas superheated, highly ionized but slowly deionizing, diffusing with relative slowness into the oil and thereby tending to prolong the cycles of arc which produce them. On the other hand, visualize an oil circuit breaker with an increased number—even a multitude—of shorter series arc gaps, each gap exposing a minimum of oil area and a maximum of electrode area and volume to the arc. Over the surface of the electrodes, by inter-reaction, the arcs are propelled to new and cooler zones. At the current zero, the arc zone is cooler, and the slowly de-ionizing hydrocarbon gases of the high-speed break are to a large extent replaced by the more quickly de-ionizing metal vapor of the electrodes.

That such a breaker—one in which a much greater proportion of the thermal energy of the power arc is absorbed and converted by the electrodes—approaches the desideratum of Dr. Slepian's paper is apparent. Initially it has the advantage derived from the condition of lower temperature as set forth in Dr. Slepian's equation (**13**) on page **4**:

---

[8] P. Phillip, *Proc. Roy. Soc.*, London A., Vol. 78, 1906, p. 167.

[9] P. F. Kovarik, *Phys. Rev.*, Vol. 30, 1910, p. 415.

$$n = \frac{1}{\alpha t}$$

which equation is another way of stating that the number of ions, or the ionic density, varies directly as the cube of the absolute temperature. It follows, with the lower temperature and the correspondingly smaller number of ions, that the rate of recovery of the dielectric strength will be much more rapid, particularly where the more rapidly de-ionizing metal vapor is, as here, in greater proportion. Finally, the increased number of arc gaps, shorter in comparison to the electrode diameter, affects a condition of reduced space charges and consequent increase in rate of recovery of dielectric strength,—this is in addition to the 200-volt equivalent increments of dielectric strength instantaneously recovered at each gap.

Such an oil circuit breaker, however, is not a design of the future. Refined and perfected in the present, it is essentially a development of the past. The multi-break oil circuit breaker with energy-absorbing arcing contacts, under test and in the field has already demonstrated the fact that it does approach the desideratum of Dr. Slepian's paper.

**J. B. MacNeill:** The paper deals with means of opening circuits radically different from those now in use. Time will tell the degree to which these ideas can be incorporated in commercial apparatus. It may be said, however, that present methods in many cases are not considered altogether adequate, and there are individual switching problems where the application of the ideas dealt with in this paper seem entirely feasible. The oil circuit breaker has been developed far beyond the expectation of the original sponsors of the device and in general is giving adequate protection on all high-voltage or high-power a-c. systems. Any oil-immersed device, however, has the inherent disadvantage due to the oil content, and substitutes for oil immersed devices will always receive any consideration they may deserve.

**F. W. Maxstadt:** (communicated after adjournment) Dr. Slepian's contribution is of interest and great value in another field than the one pointed out in the paper.

Comparatively little has been known about the mechanism of the arc used in electric arc welding, either a-c. or d-c. It is now clear that the persistence of the a-c. welding arc which operates well below 165 r. m. s. volts cannot be due to residual ionization, but must on the other hand be caused by chemical activity which is known to be oxidation of iron vapor. The fact that the arc reestablishes itself in the same path after a current zero seems to me to prove that the chemical activity extends into practically every region of the arc volume. This easily accounts for the included impurities in the deposited metal.

The well known fact that arcs between iron electrodes in an atmosphere of hydrogen require voltages in excess of 165 r. m. s. shows that chemical activity in the arc stream is, under such conditions, too small to provide a mechanism for arc reestablishment.

This suggests a line of investigation to find a gas or mixture of gases which will provide chemical activity for restarting the arc at low voltage (for safety to the operator) and yet produce no harmful compounds in the deposited metal.

The same analysis applies to the d-c. arc which oscillograms show has unsteady characteristics, with current values approaching zero for an instant and suddenly building up to normal, aided of course by the reactive voltage of the series choke put into the circuit for the purpose.

Dr. Slepian's analysis of the time-phase relations between the arc current and voltage shows that successful arc-welding circuits must have sufficient series inductance, low series resistance, low condensance (capacity) between turns of the transformer or choke and high shunt resistance across the arc. Even the conducting vapors which surround the arc, but do not take part in the arc itself, are a cause of its extinction.

# Civilization and the Engineer

## President's Address

### BY BANCROFT GHERARDI

What has the engineer contributed to civilization? Have his contributions been major factors in its development? It is important that we should know the answers to these questions, for sooner or later the standing of the engineer in the world in which we live depends upon these answers. To get them it is necessary to consider the development of civilization.

From the earliest days, mankind's primary need has been food. He cannot exist without it. In addition, in most climates he must have shelter, clothes, and fuel. As long as all human energy had to be devoted to meeting these needs, no margin remained for the improvement of man's condition, either physical, mental, or spiritual. It is to the extent that there is a margin of effort available after the minimum of these requirements is provided that civilization may develop. The existence and magnitude of such a margin has depended upon man's willingness and ability to produce beyond this minimum and the aids that he has in his work. The margin beyond that necessary for maintaining existence goes to the improvement of his status.

The students of the early stages of man's development measure the steps by which he has advanced by certain outstanding factors. Accepting the classification of Lewis H. Morgan, these are: the development of speech; the use of fire; the bow and arrow; the manufacture of pottery; the domestication of animals; the development of writing. In these, we find the beginning of civilization. And we find something more; something of the deepest significance to the engineer. Fire,—first used for warmth and cooking, and now our principal source of power. The bow and arrow—a machine by means of which man can apply his strength and dexterity more effectively. Pottery,—a manufactured article to minister to his household needs. Domestic animals,—a source of power under the control of man and a more reliable supply of food and clothing. Although at that time scientific knowledge was unknown, invention probably not recognized as such, and engineering not even dreamt of, in the bow and arrow and in pottery all were foreshadowed.

The struggle by man to learn the facts of nature and to utilize them has been slow and extended over ages. As we look back, at times progress has seemed to halt, and generally, there was no definite conception of what constituted progress or in what ways it should be sought, but nevertheless, the ground work was being laid and man was slowly moving forward.

There gradually grew up an appreciation that Nature was not whimsical or beyond understanding; that she has hidden treasures—materials and forces—that could be used by man if he would but learn what they were; that Nature was an inexhaustible treasurehouse if man would but find the "open sesame," the way to use her resources—and that the "open sesame" was to learn of Nature by studying her and not by trying to speculate what she should be; that we may theorize if our theories are based on facts and checked by experience, but that speculations without facts are idle dreams and that nothing that may be determined by observation may be safely accepted except as it is so determined. Early there were such minds,—Euclid, Archimedes, Aristarchus, Hipparchus,—but in their time they did not represent the common method of thought even of the educated people.

Then came a long period of halting, "the dark ages," during which not only did progress seem to cease, but in many cases it was discouraged by powerful authorities. But the greatest darkness always comes just before the dawn.

In the 16th and 17th centuries, the scene began to change rapidly. A number of wonderful men of whom I shall name only two, Galileo and Newton, devoted their lives to the study of nature, that is, to the getting of facts and to the effort to develop theories that would be consistent with these facts, and which could be used to postulate other facts which, if verified by observation, further extend knowledge. These men were the pioneers in our modern civilization. To these and to their successors in theory and application we owe the developments that constitute the determining factors of modern civilization.

And what are the characteristic features of the material aspects of modern civilization? They are power and machines.

Power by which man power and horsepower are multiplied to practically any extent that may be desired, and machines which, when driven by power, will make or do numberless things which man may desire. At last it is possible for man, aided by power and machinery, to produce so far beyond the primary needs of food, shelter, clothes, and fuel, that not only can he greatly improve the quantity and quality of these, but provide numberless other conveniences, comforts, and luxuries; and these results are attained today with shorter working hours than formerly were necessary to achieve a much lower standard of living.

These results have been a direct outcome of the work of the scientist, the inventor, and the engineer. And to these should be added other groups engaged in the practical application of science,—such as chemists, biologists, doctors, and architects. They have been

---

*Presented at the Summer Convention of the A. I. E. E., Denver, Colo., June 25-29, 1928.*

contributed to also by the promoter, the manager, the banker, and the capitalist—all necessary factors in the development of modern civilization but without the products of science, invention, and engineering, they could not have builded as they have. For not only is our modern civilization based upon science and its applications but these have furnished the capital necessary to realize the results attained. For capital is the margin between what we produce and what we consume for our day-by-day needs, and this margin is mostly due to the applications of science. Suppose that today China should decide that it should have transportation and a communication system equivalent in proportion to its population to that of the United States. How would it go about getting such a system promptly? There is no way that it could do so. In material and labor, this system would cost say 200 billion dollars, for highways, railroads, motor cars, and telephone plants. This could not be borrowed, because aside from any question of credit, there is no such surplus available in the rest of the world; it is not to be had, because so much has not been saved in its whole existence of several thousand years.

This brief outline of the development in the material aspects of modern civilization indicates sufficiently the part that has been taken in it by the scientist, the inventor, and the engineer. I have confined myself largely to the material aspects because the very nature of engineering has to do with physical things. Should it be inferred that the engineer has made no contribution to the mental and spirtual advance of mankind? The facts by no means justify such a conclusion.

Consider the printing press and its relations to the diffusion of knowledge. The phonograph and what it has done for music. The moving picture, and now the talking movie and their part in education and entertainment. Radio broadcasting and its bringing millions in direct touch with the finest orchestras, the greatest educators and entertainers, and enabling millions to hear the President of the United States when he speaks on a public occasion. The farm telephone and the automobile and what they have done to break down the isolation of farm life. Is the world's great transportation system—railroads, motor cars, and steamships—used solely for business? Has travel ceased to have an educational value since the slowness, expense, and discomforts of the stage coach and of the sailing ship have been eliminated from it? And our communication system—mail, telephone, and telegraph—does it contribute nothing to our higher life? Is it never used except in relation to the material aspects of life?

If such contributions to our mental and spiritual development were all that have been given to the world by the engineer and his allies, they would be notable and more than refute the statement sometimes made that the engineer's contributions are solely materialistic. But this is by no means all.

The development of culture requires leisure from the struggle for existence. Was Athens the poorest nation in the world when it developed its wonderful literature and arts? It was materially the richest of its time. Was Florence, when it developed its school of painting, a poor and struggling city? Quite the reverse. Do we look today to Patagonia or Tasmania or to the Esquimos for high mental and spiritual development? We should if material welfare was inconsistent with spiritual and mental attainments. History justifies the statement that material, mental, and spiritual development as a whole go together, and that while a genius may develop under almost any conditions, a high and distributed culture is favored by a high and distributed material welfare. The scientist and engineer have sometimes done themselves injustice in assenting to statements and occasionally even suggesting, themselves, that they have not contributed except to the material welfare of the world.

Still another outgrowth of the development of science and of its application is the educational system of today. Not always is it realized that for the maintenance of our present educational system in this country, it is a necessity that there should be a sufficiently high standard of living to permit of the withdrawal from the immediate production of the necessities of life the hundreds of thousands of teachers who are directing this educational work and the millions of students who are taking part in it. It is also necessary that there should be available huge amounts of capital to be expended for the provision of buildings and other necessary equipment. All of these have been rendered possible only by the results of applied science in increasing the margin over and above that necessary for existence.

From the beginning of history, man has constantly struggled to improve his economic status. He has wanted an assured supply of food and more pleasing food, more comfortable and better lodging, more comfortable, better, and a greater variety of clothes, better shelter, more comforts of all kinds, more leisure and recreation, and now, through the tapping of the resources of nature, year by year and decade by decade, he is attaining these ends more and more, not only for the favored few but for the great mass of the people who, but a few decades ago, were believed to be condemned by the very nature of life in this world to an existence limited to the barest necessities. This sweeping change in the economic status of individuals and nations has given rise to many questions of a fundamental character. These questions have to do with social relations, education, economics, business, health, politics, and religion. They comprehend the whole relationship of man to man and of man to his environment.

These questions do not depend for their solution upon engineering principles which so largely rest upon the characteristics of physical and inanimate things, but they have to do rather with people and with human reactions. This, however, does not take them out of the field in which the engineer must be skilled to do his work. For even though the engineer's main duty lies in the control of nature, the very organization of society which that control has given us means that the engineer, in his engineering work, must operate as a part of organized society and conduct his relations with others with due regard to human reactions. The conquest of nature on a large scale must be done by those who can use organizations of men. The modern engineer should have as great a capacity for human management, cooperation, and for dealing with others as the men in politics, religion, and other professions which are devoted primarily to the study of man. To the extent that the engineer can measure up to these requirements he may become a leader in other fields of action, as well as being a leader in his own.

Whatever may be the part of the engineer in the solution of these questions, his principal work and that which only he can do well, is to take the scientific facts made available by the scientist and, by their adaptation to practical ends, add to the welfare of mankind. And can we engineers, notwithstanding the stupendous advances of the 19th century and the gigantic steps forward of the first quarter of this century, doubt that still greater opportunities lie before us year by year, as with pride in the service that we render mankind and humility that so little has been done and so much remains to be done, we continue our work devoted to making this world a better and easier one to live in so that the burden of life may be lifted more and more from the shoulders of the average man.

# The Diverter Pole Generator

BY E. D. SMITH[1]

Associate, A. I. E. E.

*Synopsis.—This paper describes a new type of generator developed to overcome certain limitations inherent in the shunt and the compound generator, when used for charging batteries by the constant potential, the modified constant potential, and the floating methods.*

---

THE advantages of the constant-potential, the modified constant-potential, and the floating method of battery charging are quite generally recognized. These systems require a source of direct current of constant voltage.

The following characteristics are desirable in a constant potential battery charging generator:

1. It should preferably have a flat voltage curve which does not rise with increasing current at any point, otherwise stability of the correct charging voltage cannot be maintained without manual adjustment.

2. It should operate safely as a motor without speed-up or polarity reversal during feed-back from the battery.

3. It should preferably have a slight rise of voltage with decreasing current near zero load as a means for curbing a tendency to swing over to discharge during light loads.

4. When floated on bus-control circuits, which are subject to heavy momentary loads, at some point above full load the voltage should abruptly droop to protect the generator from the high peaks by shifting them to the battery, otherwise the generator will be damaged.

5. After the occurrence of these peak loads the generator voltage should return to its original value.

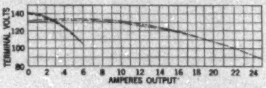

FIG. 1—VOLTAGE REGULATION CURVES OF 1½-KW. 130-VOLT SHUNT AND COMPOUND GENERATORS

———————— increasing load shunt generator
- - - - - - - - - - - decreasing load shunt generator
-.-.-.-.-.-.-. increasing load compound generator
-..-..-..-.. decreasing load compound generator

NOTE.—With shunt generator the voltage comes back slightly lower after an overload while the compound generators voltage comes back slightly higher after an overload

6. Commutation and efficiency should compare favorably with current standards.

The shunt generator is inadequate as its voltage falls too greatly with increasing load. Voltage regulators, when sufficiently sensitive, are necessarily delicate, and being susceptible to external conditions are difficult to keep properly adjusted.

The compound wound generator fulfils some of the conditions but has its limitations. In case of feed-back from the battery the generator will motorize and run at an excessive speed and thus may cause damage. This is due to reversed current in the series coils bucking the shunt winding and lowering the field strength.

Also, the voltage curve, Fig. 1, of a flat compound generator is too convex for constant potential battery charging. With this typical curve it is difficult to charge at any rate between zero and that corresponding to the maximum voltage point, unless resistance is interposed between the generator and battery. In fact, any reduction of the charging current below the value corresponding to maximum voltage will usually be followed by a downward surge to discharge.

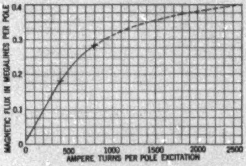

FIG. 2—MAGNETIZATION CURVE

———————— in producing the regulating flux in the diverter pole generator the magnetic changes are confined to the diverter pole and take place on this part of the curve
- - - - - - - - - - - in producing the regulating flux in the compound generator the magnetic changes occur in the main magnetic circuit and take place on this part of the curve

The voltage characteristic of the compound generator is curved, since the necessary magnetic changes produced by the series winding take place in the main magnetic circuit in accordance with the magnetization curve of the machine, (Fig. 2). Usually in obtaining satisfactory design it is necessary to work at least partly on the curved portion of the magnetization curve and the compound generator reflects this curvature in its voltage characteristic.

The following is a description of a generator designed for the specific purpose of meeting the exacting requirements necessary in a constant potential generator for battery charging:

In this generator, as shown in Fig. 4, a small diverter pole (1) spaced midway between the main poles, has a magnetic bridge connecting it to one of the main poles. Magnetic flux from the main pole will leak across this bridge to the diverter pole. A restricted section at 2

---

[1] Rochester Elec. Products Corp., Rochester, N. Y.

*Presented at the Northeastern District No. 1 Meeting of the A. I. E. E., New Haven, Conn., May 9-12, 1928.*

in this bridge performs two functions: first, it limits the leakage, and second it serves as a magnetic choke, whereby it is possible to regulate the magnetism passing to the armature from the inner face of the diverter pole at 3. This regulation is possible since practically the whole of the main field ampere turns acting on the diverter pole are concentrated in overcoming the reluctance at this one restricted section, so that any reduction of the flux through this restricted section will release ampere turns expended here and raise the magnetic potential at 3 and consequently increase the magnetism passing to the armature at this point. At no load substantially all magnetic flux crossing the bridge will take the low reluctance path through the diverter pole (1) back to the frame without pausing through the armature. A coil in series with the load circuit surrounds the diverter pole. This coil, as the load current increases, opposes and reduces the passage of magnetic flux through the diverter pole (1) to the frame.

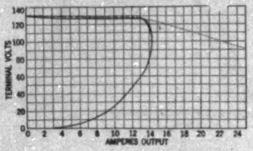

FIG. 3—VOLTAGE REGULATION CURVES OF 1½-KW. 130-VOLT DIVERTER-POLE CONTROL-BUS GENERATOR

- - - - - - - decreasing load self excited
. . . . . . . . . increasing load separately excited

NOTE.—The voltage comes back slightly higher after an overload

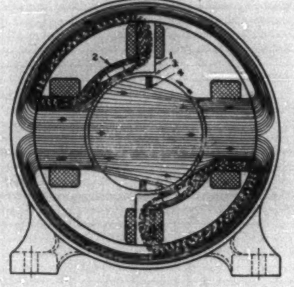

FIG. 4—MAGNETIC FLUX DISTRIBUTION AT NO LOAD

———— main flux
- - - - - - - leakage flux

The decrease of flux through the restricted section at 2, attending any reduction of flux through the diverter pole, (1), produces, as above stated, a rise in the magnetic potential at 3. The result is that part of the magnetic flux leaking across the bridge will take the air-gap path to the armature at 3 (Fig. 5), adding its value to the main pole flux and compensating for the voltage drop in the generator.

No variation of flux from the main pole to the armature occurs as there is no change in the magnetic potential at the main pole air gap. This follows, since neither the main pole nor the frame is highly saturated and the small variation of flux through these parts, due to the change of flux through the diverter pole, produces no appreciable variation in ampere turns of the main field excitation expended on this part of the main magnetic circuit.

A flat voltage curve is obtained since the magnetic changes produced by the series winding take place only in the diverter pole (1), and as the flux density here is kept low these changes occur on the low straight portion of the magnetization curve, thus eliminating most of the curvature from the generator voltage characteristic. These magnetic changes occurring in the diverter pole take place from a higher to a lower density on increasing the current output of the generator. This is the reverse of the occurrence in the compound generator, and the effect is to invert whatever part of the magnetization curve appears in the generator voltage characteristic, producing a concave instead of a convex voltage curve. By the proper adjustment of the diverter pole winding an almost straight curve is obtained with a slight rise on approaching zero load.

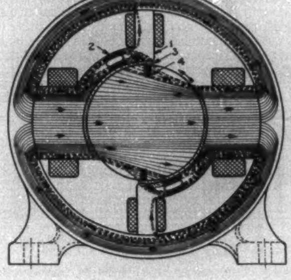

FIG. 5—MAGNETIC FLUX DISTRIBUTION AT FULL LOAD

———— main flux
- - - - - - - leakage flux

When motorizing, the main field strength is maintained substantially at its full value, as reversed current in the series coil can divert no further leakage due to saturation of the bridge restriction at (2). Also, any tendency for the diverter pole (1) to establish itself as an independent pole opposite in polarity to the main pole is limited to a safe value since the diverter pole already carrying the leakage flux quickly approaches saturation at any increase of flux through it, and safe operation as a motor is assured.

At some value of the load current the ampere turns on the diverter pole equal those on the main pole and at this time the magnetic flux leaking across the bridge to the diverter pole is all re-diverted across air-gap 3, and there is no further leakage flux for an increased current to re-divert to the armature.

What occurs when the load is increased beyond this point is best illustrated by some recent tests.

The machine tested was a 1½-kw. generator, designed for floating with a 129-volt bus control battery. For the tests, this generator was equipped with a pair of movable exploring brushes by which the voltage around the commutator could be checked step by step and the flux distribution determined.

Fig. 6 shows the flux distribution when the generator was operating with brushes up, shunt fields separately excited at a constant value and various currents passed through the diverter pole coils. This shows that the regulating flux is produced only at the diverter pole face, the flux from the main pole remaining practically constant.

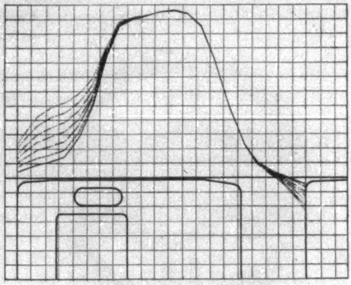

Fig. 6—Flux Distribution Curves

When excitation of diverter poles is increased, armature carrying no current, brushes up, with main fields separately excited at constant value

——————— 0 amperes in diverter pole coils

-..-..-..- 15 amperes in diverter pole coils
.......... 20 amperes in diverter pole coils
——— . . . . ——— 25 amperes in diverter pole coils
——— . . . . . ——— 30 amperes in diverter pole coils

Figs. 7 and 8 illustrate flux distribution under load, Fig. 7 showing flux changes up to the voltage cut-off point of 14 amperes. This shows the effect of armature reaction in the crowding of the main field to the right and in the partial suppression of the diverter pole field.

Fig. 8 shows that with any increase in the load current beyond the cut-off value of 14 amperes, instead of an increase in the diverter pole field there is a definite and decided collapse. With this collapse of the diverter pole field the terminal voltage falls and hence the main field excitation is reduced which accounts for the reduction of the main pole flux. The solid line of Fig. 3 shows the voltage regulation for this machine.

Fig. 9 represents flux distribution under conditions similar to those of Fig. 8 except that here the main fields were separately excited and maintained constant during the test. The broken line of Fig. 3 shows the voltage regulation for this machine.

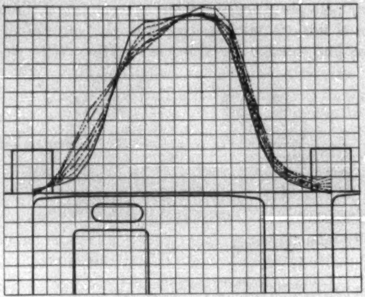

Fig. 7—Flux Distribution Curves

When output is increased up to the voltage cutoff point at 14 amp. with main fields self excited

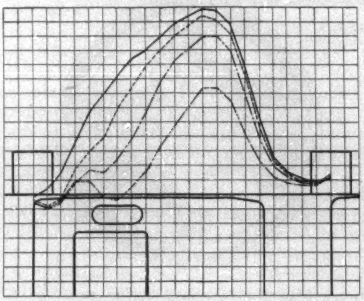

Fig. 8—Flux Distribution Curves

When diverter pole generator is loaded beyond the voltage cutoff point at 14 amp. with main fields self-excited. Although the load was increased the amperes decreased due to the falling voltage

——————— 14 amperes generator output
- - - - - - - - - - 14.4 amperes generator output
-.-.-.-.-.- 14 amperes generator output
-..-..-.. 11.2 amperes generator output

This test also shows the collapse of the diverter pole field when the load current is increased beyond the 14-ampere point at which the ampere turns on the diverter poles equal those of the main pole.

It appears from these tests that when the ampere turns on the diverter pole exceed those on the main pole, the flow of magnetism through the diverter bridge is reversed. Magnetism now flows from the diverter pole to the main pole and not from the main pole to the diverter pole. Under these changed conditions the magnetizing action of the armature assists the flow of magnetism through the bridge instead of opposing it. In fact, under heavy loads the magnetism does actually reverse and pass from the armature to the bridge, and joining with the main pole flux, passes back to the armature at the hindward pole tip, constituting cross magnetism, while the magnetism from the diverter pole crossing the bridge flows backward through the main pole to the frame returning to the diverter pole without passing through the armature.

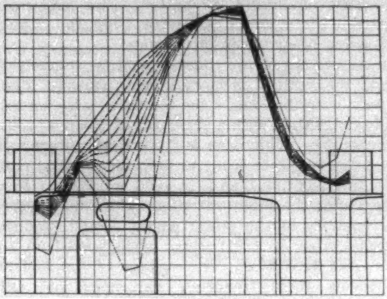

Fig. 9—Flux Distribution Curves

| -........- | 45 amperes generator output |

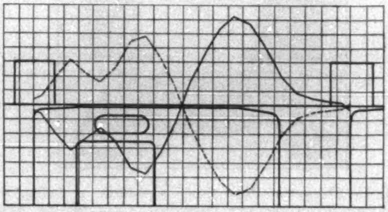

Fig. 10—Flux Distribution Curves

During short circuit of diverter pole generator with main fields self-excited. The flux pulsates between the values shown by the solid and broken line curves

This theory requires the co-existence of two opposite magnetic fluxes in the main pole and also in the frame. However, it is the only apparent explanation of the definite collapse of the diverter pole field occurring with each increase of the diverter pole ampere turns above those of the main pole.

Fig. 10 shows flux conditions during short circuit, the flux pulsating between the values shown by the solid and broken line, the voltage and current pulsating also between the positive and negative values of 0.7 volts and 19 amperes.

Fig. 11, which represents conditions when generator is operated as a motor, shows some distortion of the main field due to armature reaction and a slight reduction of the diverter pole field due to reversed current in diverter pole coils, this reduction being insufficient, however, to cause any instability in speed when motorizing.

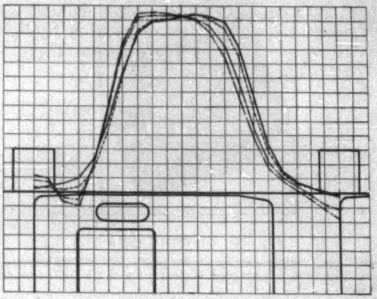

Fig. 11—Flux Distribution Curves

When diverter pole generator is operating as a motor with varying load

| | |
|---|---|
| ———— | 0 ampere output as generator |
| --------- | 3 ampere input as motor |
| -.-.-.-.- | 10 ampere input as motor |
| -..-..-..- | 15 ampere input as motor |

When the load on the generator decreases a descending excitation is produced in the diverter pole coils and due to the effect of hysteresis this descending excitation leaves a slight residual magnetic field passing from the diverter pole face to the armature. This accounts for the voltage being slightly higher after an overload than before, as shown in Fig. 3.

Good commutation is assured as the diverter pole provides a commutating field of the correct direction for improving commutation and this field varies with the current output as in an interpole generator.

The efficiency will equal that of a similarly rated compound interpole generator since the excitation on the main poles will equal the shunt and series excitation and diverter pole excitation will be the same as that of the interpole of the compound generator.

Figs. 12 and 13 illustrate the pole and the complete field assembly of the diverter pole generator.

The characteristics of this generator are desirable for many battery charging applications.

In telephone exchanges when floated in parallel with the main battery, the generator maintains the voltage within the close limits required for correct operation of the equipment and furnishes the current directly to the exchange without its passing through the battery. Considerable economy is effected by the saving of power and in the increased life of the battery, and also by a saving of labor through the elimination of the necessity of manual voltage regulation.

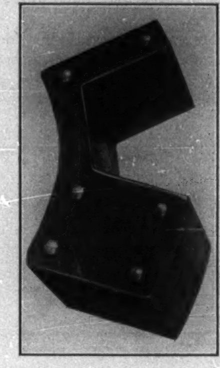

Fig. 12—Diverter Pole

The hole in the bridge does not appear as the two end laminations are punched without this hole the inner laminations have the hole as shown in Figs. 4 and 5

When several batteries are charged in parallel by the constant potential or modified constant potential method, as in recharging of vehicle and automobile batteries, the advantage of constant voltage, coupled with the ability to operate safely as a motor without polarity reversal or speed up during power failure is quite apparent.

In control bus operation, where a small generator is connected and operated continuously in parallel with a battery for switch operation, all of the desirable characteristics of this generator are utilized to advantage.

The flat voltage characteristic insures maintenance of correct floating voltage under varying load conditions with minimum supervision.

The ability to motorize safely without speed up or polarity reversal gives security during power interruptions.

The slight rise in voltage with decreasing current near zero load and the recovery momentarily to a slightly higher voltage after an overload combines to produce the desired stability of the correct floating voltage at the light load which constitutes the normal operating condition.

The sharp droop in the voltage just above full load amply protects both the generator and motor from danger of overload during switch operation.

The high voltage recovery after overload prevents the gradual diminishing of the generator voltage and consequent discharge of battery that occasionally happens with a shunt generator from the repeated overloading occurring in this service.

An advantage of the constant-voltage characteristic is that the battery is more quickly charged after it has been carrying load, since the battery is charged at a higher rate than with a generator of drooping voltage characteristic. This is an additional advantage as the higher charging rate tends to keep the battery, particularly the negative plates, in good condition. It also appears that the slight variations which may occur in the frequency of the power circuit should produce a beneficial effect in the battery when floated on a diverter pole generator. The voltage of the generator will follow these frequency variations and either slightly charge or discharge the battery as these variations are above or below normal. This will give a desired amount of activity to the negative plates without overcharging the positive plates.

It might appear that a generator with a drooping voltage characteristic is desirable for this floating method since the charging current is less affected by speed variations of the driving motor. However, as these generators are usually driven by induction motors their speed is not affected by variations in voltage, variations in frequency being the only cause of speed variation. Since the frequency of modern commercial power circuits is held within very close limits, no objectionable variation of motor speed is encountered which would justify the use of a drooping voltage generator for its damping qualities.

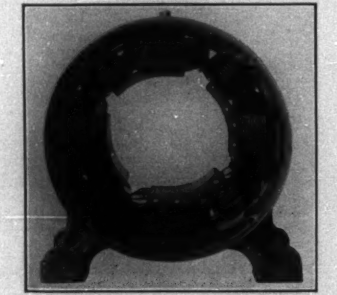

Fig. 13—Diverter Pole Field Assembly of a 7½-Volt Generator for Constant Potential Charging of Automobile and Radio Batteries

The battery discharge during switch operation is not so great where the diverter pole generator is used, since the generator supplies the current demand up to its full load capacity, while the shunt generator gives little assistance to the battery at this time. This means that a higher bus voltage will be maintained during switch operation with the same size battery when floated with a diverter pole generator.

In some power applications, as for instance, car retarder operation, the load demands, while still intermittent, are more frequent and of longer duration so that the equivalent continuous load is a greater percentage of the battery capacity.

In this case it is desirable to restore the battery charge as much as possible between the heavy demands and it is also desirable that the bus voltage be maintained under varying load so that uniform response will be assured at the various control stations.

The generator designed for this application absorbs all loads up to 200 per cent of its normal rating, maintaining constant bus voltage up to this point and the battery is only called into action during loads in excess of this value.

Several thousand of these generators have been built and are operating on various battery charging applications, and their performance has justified the conclusion that the generator has many advantages where the constant potential, modified constant potential, or the floating method of charging is used.

The outstanding feature of this machine is its ability to give constant voltage with varying load and still be safe from speeding up or polarity reversal during feedback from the battery. However, the other characteristics, *viz.*, the inverting of the voltage curve which makes for stability of the charging voltage, the high voltage recovery after overload insuring voltage stability on light loads, and the drooping of the voltage on overload which protects it from serious overloading, contribute to its adaptability to the battery charging field.

# An Amplifier to Adapt the Oscillograph to Low-Current Investigations

BY SIGMUND K. WALDORF[1]

Associate, A. I. E. E.

***Synopsis.***—*There has been need in several fields of electrical engineering research for a means to study time relations, wave forms, and similar phenomena where only infinitesimal currents are obtainable. The limitations and advantages of several possible methods of investigation are briefly compared, and the conclusion reached that the ordinary oscillograph can be most profitably adapted to such work.*

*The best form of vacuum tube amplifier for the work is then discussed, followed by a description of the steps taken in the design of a suitable resistance coupled amplifier. This amplifier is then described.*

*The results of tests showing quality of reproduction are given in the form of oscillograms and a characteristic curve. The recommended procedure to be followed and the necessary precautions to be observed in the use of the amplifier are given, with a short discussion of the abilities and possibilities of the oscillograph in its widened field of usefulness.*

* * * * *

## INTRODUCTION

THE ordinary type of oscillograph, operating on the D'Arsonval principle, has proved of great value in many fields, but the currents required to give workable deflections are so large as to restrict its use to cases where the available currents are greater than approximately a twentieth of an ampere. To obtain fairly large deflections, about a tenth of an ampere is necessary for alternating currents and almost a fifth for continuous currents. For low current investigations, where the currents are less than these values, one must look around for other means or apparatus to meet the requirements. The cathode ray oscillograph or the Einthoven string galvanometer might be mentioned, but they have several serious limitations for engineering problems for which the usual type of oscillograph has desirable characteristics. For combined sturdiness, ease of operation, transient recording, simultaneous multiple recording, and general utility the oscillograph far surpasses these other instruments.

Thus it has been thought worth while to adapt the oscillograph to small currents by means of a suitable vacuum tube amplifier. Such amplifiers are in common use for many purposes, so that their various forms and principles of operation are now widely known. The particular problem in this case was to obtain perfect reproduction over the entire frequency range of the oscillograph, a requirement calling for the careful selection of the proper circuit and careful subsequent design and construction. An amplifier circuit utilizing transformers cannot be expected to give perfectly equal amplification of all frequencies over a wide range. This can be predicted from theoretical considerations and has been shown experimentally in the unpublished effort of another investigator using a resistance coupled amplifier with a transformer in the output circuit. The purpose of this transformer was to obtain sufficient oscillograph current without requiring excessive plate current from the output vacuum tubes.

With this in mind, the resistance-capacity coupled and the straight resistance coupled amplifiers are the only ones that can be expected to give faithful amplification over a wide range of frequencies, so these were the only two seriously considered here. As will be seen later, the resistance coupled circuit was the only one found to be entirely satisfactory for all frequencies for which the oscillograph can be used, and it has the additional advantage that it amplifies continuous currents as well as alternating. The amplifier which has been built and is described in this paper will therefore meet all frequency conditions for which the oscillograph is applicable.

## PRELIMINARY DESIGN AND TESTS

After it was decided to try the resistance-capacity coupled amplifier first, a survey was made to determine which of the many kinds of available vacuum tubes were best suited to the purpose. The Western Electric 102-D and 104-D tubes were thought to be the most desirable. Their nominal ratings as furnished by the manufacturer are given in the following table.

VACUUM TUBE RATINGS

| | 102-D | 104-D |
|---|---|---|
| Normal filament current (amperes.) | 0.95 | 0.97 |
| Normal filament voltage | 2 to 2.5 | 4 to 5 |
| Normal filament voltage | 2 to 2.5 | 4 to 5 |
| Normal plate voltage | 100 to 150 | 100 to 150 |
| Normal grid voltage | 0 to − 3 | −15 to − 30 |
| Normal plate current (milliamperes) | 0.3 to 1.5 | 10 to 30 |
| Plate-filament impedance (ohms) | 40000 to 100000 | 1500 to 3000 |
| Amplification constant | 26 to 34 | 2 to 3 |
| Maximum safe plate voltage | 160 | 160 |

The plan for the amplifier was to place the input on the grid of a 102-D tube and have the plate circuit of

*Initial and Best-Paper prize paper, presented at the Meeting of the Baltimore Section, District No. 2, Baltimore, Md., April 22, 1927.*

this tube act on the grids of a number of 104-D tubes with their grids, filaments, and plates connected in parallel. The oscillograph element was to be connected directly into the combined plate circuit of these 104-D tubes. As no transformers were to be used anywhere in the circuit because of possible distortion, the 102-D tube was chosen for the first stage for its high amplification constant, and the 104-D tubes for the second stage for their high current output at relatively low plate voltage. As it could be seen that the plate current requirements of the output tubes would be severe, the parallel arrangement in the output stage was called for. The power requirements of both these types of tubes are not exceptional and can be handled easily.

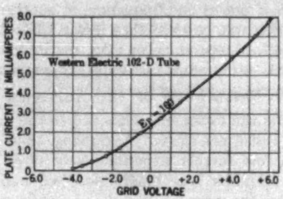

Fig. 1—Typical Characteristic of a Western Electric 102-D Vacuum Tube with Negligible External Plate Impedance. Plate Voltage = 160

The characteristics of the two types of tubes were taken with the plate milliammeter the only external plate impedance, holding the applied plate voltage constant at the maximum safe value (160 volts). These characteristics are given in Figs. 1 and 2. The characteristic curves of the 102-D tube were then taken with appreciable external plate impedance to determine the proper resistance to give a perfectly straight characteristic. After a few trials, a plate impedance of approximately 25,000 ohms was found to be the proper value, giving a straight characteristic for negative grid potentials between zero and approximately three and a quarter volts. Under these conditions the voltage variation across the plate impedance was slightly more than 28 volts, as calculated from the plate impedance and the change in plate current.

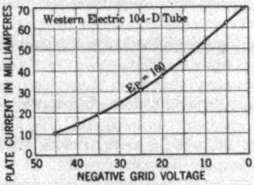

Fig. 2—Typical Characteristic of a Western Electric 104-D Vacuum Tube with Negligible External Plate Impedance. Plate Voltage = 160

The characteristics of the 104-D tubes indicated that these tubes would give straight line reproduction in use if the total grid voltage variation did not exceed a maximum value of 30 volts, varying from − 3 to − 33 volts.

A resistance-capacity coupled amplifier was then made up using the connections of Fig. 3. This was in two stages—the first designed for voltage amplification with the 102-D tube, and the second for maximum possible current output with two 104-D tubes in parallel. The bias on the first stage was − 1½ volts and that on the second was varied from − 15 to − 22½ to determine the most suitable value. The plate impedance of the first tube was two lavite resistance units in series, of 25,300 ohms total resistance. The two-microfarad coupling condenser was an ordinary telephone condenser of waxed paper and tinfoil. The grid leak was ordinarily 100,000 ohms of lavite resistors, but was varied from about 140,000 to about 40,000 ohms to find the best value. Other necessary information is given in the diagram of Fig. 3.

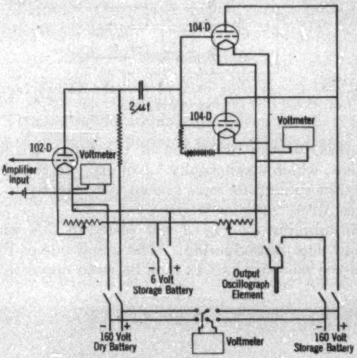

Fig. 3—Connections of the Trial Resistance-Capacity Coupled Amplifier

To test the quality of reproduction of the amplifier, it is necessary that the input wave form be recorded as well as that of the output, and that the input as indicated by the input oscillograph element be absolutely the same as that impressed on the amplifier input. To attain this, the input connection shown in Fig. 4 was used for all tests of reproduction. The 57- and the 355-ohm resistances were tube rheostats used as a potential divider to give the desired voltage across the 4-dial resistance boxes. This voltage was read on a General Electric Type P3 voltmeter with a 30 volt range. The resistance $R_G$ was zero in the earlier tests but had values up to 105,000 ohms in the tests of reproduction of the final amplifier. Its function in the input grid circuit will be explained later.

In order that all the conditions of testing should be known in the earlier work, a sine wave was used for the input. The potential divider was adjusted to give exactly 21.2 volts on the 30-volt voltmeter, which gave a peak value of 30 volts across the 4-dial resistance boxes. This gave a total voltage variation across these boxes of 60 volts between opposite alternating wave peaks. For example, in the first test it was desired to have an input grid variation of exactly three volts. Using 20 ohms per volt based on peak values, $R_1$ was dialed to 30 ohms and $R_2$ to 569 ohms. This value of $R_2$ allows one ohm for the resistance of the input oscillograph element, which was actually 1.5 ohms. In this manner, the input conditions were known very exactly to be the desired three volts variation.

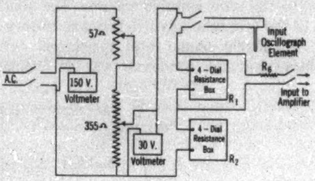

FIG. 4—CONNECTION USED TO IMPRESS KNOWN INPUT ON THE AMPLIFIER

The amplifier of Fig. 3 was tested in this way and showed poor reproduction. The amplitude of the output wave was only half an inch between opposite peaks, and showed a decided flattening effect on waves of one side and a peaking effect on those of the opposite side.

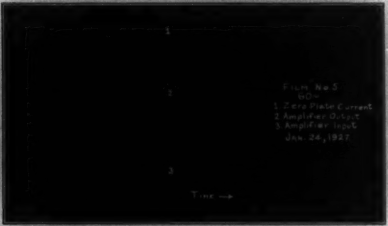

FIG. 5—DISTORTION OF A 60-CYCLE SINE WAVE BY THE OUTPUT STAGE OF THE TRIAL RESISTANCE-CAPACITY COUPLED AMPLIFIER

To determine which stage of the amplifier was responsible for the distortion, the first stage was removed and 30 volts grid variation placed directly on the 104–D tubes through their coupling condenser and grid leak. To increase their plate output, a third tube was added in parallel to the other two, and the three operated under these conditions gave an amplitude of approximately an inch. The distortion was still decidedly present, as can be seen in Fig. 5. The straight line marked "1" on this oscillogram was obtained when the output oscillograph element was disconnected from the output plate circuit and no current flowed through it.

Further similar trials were made with this form of amplifier, investigating the effects of various values of coupling condensers, grid leaks, grid bias, and variations of grid input potential. But even at relatively small amplitudes the distortion was very apparent, if not at one frequency, at another. Finally the decision was reached that it was quite hopeless to attain perfect reproduction over the desired range of frequencies using resistance-capacity coupling.

### FINAL FORM OF THE AMPLIFIER

Utilizing the experience obtained in the experiments on the resistance-capacity coupling, and with the aid of a few further experiments, a plain resistance coupled amplifier was finally designed and built according to the plan of Fig. 6. As there are several interesting features included in this amplifier, it will be described in some detail.

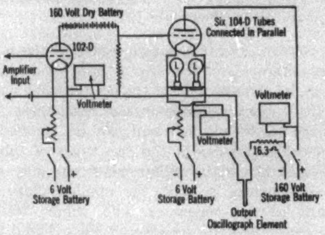

FIG. 6—FINAL FORM OF THE PURE RESISTANCE COUPLED AMPLIFIER

It is necessary that each stage have its own set of filament and plate batteries. The battery requirements of the first stage are not unusual. The filament voltage of the 102–D tube is kept at 2.25 volts and draws about 0.9 ampere filament current. A 6-volt filament storage battery is used simply for convenience, as the usual commercial storage battery has three cells. Naturally, a 4-volt battery would be just as satisfactory for the purpose. The plate battery for this stage is seven blocks of the usual 22½-volt radio B batteries. Using fresh batteries, the plate voltage is very close to 160 volts. These batteries should maintain this voltage for considerable time as the current drain is only a little over a milliampere.

The battery requirements are much more severe in the second or output stage. The current drain on the 6-volt filament storage battery is 6.25 amperes when the filament voltage is held at the fixed operating value of 4.5 volts. The filament rheostat is two 15-in. lengths of No. 18 advance wire, suspended together in parallel between two porcelain insulator knobs. The slider is a 15-ampere battery clip with a lead from the negative battery terminal. One end of the resistance wires is connected to the common negative filament lead.

The plate battery is a heavy-duty radio storage battery with a current rating of a quarter of an ampere. This battery has a number of end cells so that the voltage can be maintained at 160 volts. When the amplifier is in operation, the terminal voltage of this battery falls off two or three volts due to the internal resistance of the cells. When the additional plate impedance was placed in series with the output oscillograph element, this was kept in mind. If the storage battery were of sufficient capacity to maintain constant voltage, this extra resistance would be made greater than 16.3 ohms. Because of this slight voltage variation, it has been found desirable to have the plate voltmeter connected across this battery all the time it is in operation, so that the plate voltage may be noted at any time.

The added plate resistor of 16.3 ohms was found necessary to help straighten the characteristics of the 104–D tubes. As it must carry as much as a quarter ampere it is made of No. 24 double cotton-covered advance wire wound non-inductively on a wooden spool. A further aid in straightening the characteristic is the potential divider arrangement of the two incandescent lamps *LL* in series across the tube filaments. When under operating conditions the maximum plate current is drawn from each tube, the plate current is of the order of seven per cent of the normal filament current. If all this flows into the filament at one end there will be excessive heating of the filament at this end. There will then exist an appreciable change of the filament temperature with change in plate current, causing an irregular amplifier characteristic. Providing two parallel paths for the plate current reduces this effect to a minimum by giving a more even division of the current between the two ends of the filament.

Using a potential divider of two 200-watt, 120-volt, Mazda C lamps as shown, actually improved the operation of the amplifier considerably. Of course, besides having the effect described, these lamps are additional resistance in the output circuit, thus serving a double purpose. The lamp resistance varies with the applied voltage, but with the constant filament voltage maintained, their combined series resistance was found to be fixed at about 15 ohms.

The negative grid bias on the 102–D tube is 1.6 volts furnished by a single small flashlight cell. No bias battery is needed on the 104–D tubes; the proper bias is furnished by the drop across the plate impedance of the 102–D tube. The voltage drop across this plate impedance ranges from 4.9 to 33.1 volts in the working interval. This impedance is 24,500 ohms pure resistance of two lavite cylinders in series.

To reduce to a minimum inductive and capacity effects which are troublesome at the higher frequencies, the amplifier has been made as compact as possible. The amplifier itself, with its tubes, lamps, resistances, and miniature filament voltmeters, is all mounted on a board 25 by 12 in. The dry B batteries, the two filament and the input switches, and the plate voltmeter (of the regular larger size) are on the table supporting the amplifier board. The total table space used is 29 by 34 in., which allows space to spare. The two filament storage batteries and the plate storage battery are placed on the floor beneath the table. Provision has also been made to charge the filament storage batteries easily by the use of double-pole, double-throw switches in place of the single-throw filament switches of Fig. 6. To avoid unimportant complications, these connections have not been shown on the amplifier diagram. Otherwise, the amplifier is as simple as the diagram indicates.

## TESTS OF REPRODUCTION

The performance of an amplifier under all possible conditions must be, necessarily, the criterion of its worth. This particular amplifier has been tested under a number of differing conditions and has been found to have excellent properties.

As the amplifier is to work with the oscillograph, all tests were made considering the combination as a single unit designed to record low-current phenomena. The conditions on the oscillograph as well as those on the amplifier were kept under close observation. For all tests, the tensions on the oscillograph elements were kept at five ounces, and when observations were made, the galvanometer field current was kept at the rated saturation value of 0.35 ampere or slightly above.

Resistance coupling is a d-c. amplifier circuit and permits of taking a static characteristic curve. This was done, (for results see Fig. 7) where the sensitivity of the output oscillograph element was 40 milliamperes per centimeter deflection. As can be seen, straight line reproduction is obtained for grid potentials between zero and $-3.2$ volts, with a total change of oscillograph deflection of 5.2 centimeters. With a grid bias of $-1.6$ volts on the input, operation takes place in the middle of this range. In tests where the input wave form is unknown, the amplitude is kept well within these limits, so that any peaks present will not be distorted by being beyond the straight portion of the curve.

The static characteristic curve brings out an interesting property of this amplifier, which is that the amplifier cannot be seriously overloaded. This is due to cut-off occurring in either the first or second stages when the input grid potentials become excessive. The phase of the input is reversed in the output, that is, an increase of input grid potential decreases the output current. If the input grid is given an increase in potential, the plate current of the 102–D tube increases with a consequent decrease in the potential of the 104-D tube grids. This decreases the output current. If the input voltage is too high, the output grids become sufficiently negative to cause close to cut-off in the 104-D tubes. If the opposite condition should occur, the input grid becoming strongly negative, the plate current of the 102-D tube will be very small and the output grids will approach zero potential, which they cannot exceed. This limits the output current to that which the 104-D tubes furnish with zero grid potential. Although this may damage the oscillograph element if left on for any time, the amplifier should not be affected.

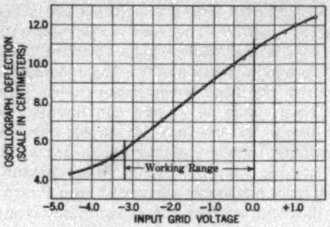

Fig. 7—Characteristic of the Combined Vacuum Tube Amplifier and Oscillograph

Tests were made with alternating currents over a wide range of conditions. It is here that the resistance $R_G$ in the input grid circuit serves an important purpose. (See Fig. 4) This was given values from zero to 105,000 ohms. If the grid currents were of the same order of magnitude, or even somewhat smaller than the currents to be amplified, there would be distortion introduced when the grid circuit impedance is made very high. The effect of this grid impedance is not noticeable for any values within these limits. The oscillograms shown are with this high resistance inserted. This amount was used because the author was most interested in the behavior of the amplifier when the currents to be amplified are of the order of five to ten microamperes, or larger. With these small currents the necessary circuit resistance to be inserted to obtain proper input grid potential variations is of about the stated value. If it is desired to amplify smaller currents than this, or the available voltage variation is too low to give good oscillograph amplitude, a third stage may be placed on the amplifier, identical with the 102-D stage and acting on this stage with the necessary change of grid bias. Under such conditions the input voltage variation need be only little more than a third of a volt and the amplifier currents possibly of the order of a microampere for maximum amplitudes.

Fig. 8—Reproduction of a 60-Cycle Sine Wave

Figs. 8 and 9 show the quality of reproduction of the amplifier with a sine wave impressed. The straight lines on these figures are the zero lines of the input voltages; no zero lines were taken on the output. The amplitudes of the output waves are two inches, which is about the limit for perfect reproduction. It should be borne in mind that the relative amplitudes of the input and output waves have no significance, as the size of the input wave depends on the ohms per volt in the four-dial resistance boxes of the input connection, whereas the output wave depends upon the input grid voltage variation.

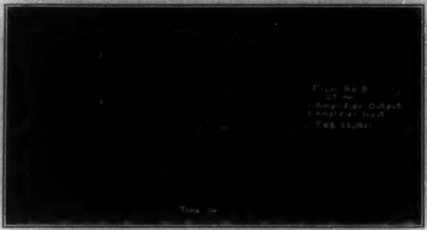

Fig. 9—Reproduction of a 25-Cycle Sine Wave

Fig. 10—Reproduction of a 58-Cycle Alternating Wave of Irregular Form

Fig. 10 shows the reproduction of an a-c. wave with slot ripples present on the peaks; Fig. 11, a fairly smooth wave taken at a higher frequency, where the wave forms of the cycles varied. The amplitude on Fig. 10

is 1¾ in. between opposite peaks; that on Fig. 11 is 1½ in.

Fig. 12 is of special interest as this is a record of a transient phenomenon of very irregular wave form. As the form of the wave was unknown, when the record was being made, the amplitude of the light spread of the oscillograph was widened until it was about 1½ in., by increase of the resistance across which the input was connected. This allowed ample room on the straight portion of the amplifier characteristic for any peaks that might have been present and not apparent on the stationary ground glass scale. Then the film was exposed and the record obtained. The arrow points to a short oscillation which occurred and which was reproduced very well. As this oscillation is at about 4500 cycles and is amplified satisfactorily, it is indicated that the amplifier will take care of all conditions which the oscillograph itself can handle properly at the higher frequencies.

FIG. 11—REPRODUCTION OF A 135.5-CYCLE ALTERNATING WAVE OF VARYING FORM

A careful study of these tests shows that the amplifier described gives identical reproductions and that it is competent to extend the range of the oscillograph down to five or ten effective microamperes at one effective volt on alternating current, or slightly higher voltage on direct current.

FIG. 12—REPRODUCTION OF A VERY IRREGULAR TRANSIENT ALTERNATING CURRENT

The arrow indicates the presence of a damped oscillation of approximately 4500 cycles per sec.

## PROCEDURE AND PRECAUTIONS

A few words should be said concerning the actual use of the amplifier. It is believed that it has been reduced to its simplest possible form and that apparatus requiring the operator's attention is at a minimum. The observations and tests described have been made by a single operator without difficulty. The ordinary care exercised in the use of the oscillograph and of vacuum tubes should be sufficient for the proper operation of the combined amplifier and oscillograph.

FIG. 13—ACCENTUATION OF HIGHER HARMONICS BY THE AMPLIFIER DUE TO UNDULY LONG PLATE BATTERY LEADS

Whenever the amplifier is used, the input grid battery and the dry cell plate battery should be tested to see that their voltages are correct. The grid battery, especially, should be watched and not allowed to get below approximately 1.54 volts. If the maximum amplifier output is to be obtained at all times, it has been found advisable to hold this grid bias close to 1.60 volts.

FIG. 14—AN APPLICATION OF THE AMPLIFYING OSCILLOGRAPH TO A HIGH-VOLTAGE D-C. INVESTIGATION

The filament and plate storage battery voltages should be kept as close to the proper values as convenient. Slight changes in these have not been found to cause distortion if such changes do not occur during the interval when the film is being exposed.

As mentioned previously, if a storage battery is available for the plate supply of the 104-D tubes which has sufficient capacity to maintain its voltage, the value of the additional resistance in the output circuit must be made greater than 16.3 ohms by about 8 ohms. Of course the exact value must be determined by experiment in any particular instance.

To lengthen tube and oscillograph element life, the output circuit should be closed only so long as is necessary for proper adjustments and observations. It is advisable also to turn off the filaments of the vacuum tubes as soon as convenient.

An interesting effect of unduly long leads is illustrated in Fig. 13. When not in use on the amplifier, it was desired to use the plate storage battery for other work, so about 150 ft. of insulated twisted pair were run from the battery to the other apparatus in question. Shortly after this had been done, the test of reproduction was made which is shown in Fig. 13. The irregularities of the input are much exaggerated in the output, indicating over-amplification of the higher frequencies. This new development in the amplifier was puzzling until the presence of the additional long leads came to mind. They were removed and the reproduction returned to its former good quality. The explanation of this effect is that the long twisted leads acted as a by-pass condenser across the plate battery for the higher frequencies.

An instance of the usefulness of the amplifier is given in Fig. 14, which is a test made to observe the commutator ripple of a high-voltage d-c. generator when shunted by condensers. Some research was in progress for which it was desirable to determine what could be done to remove the ripple of a 15,000-volt machine. The oscillograph was the logical means to employ for observation of the ripple, but as the oscillograph ordinarily requires about a tenth of an ampere for such indications, it is difficult to obtain and handle resistance for this current and voltage to be placed in series with the oscillograph element. So a suitable resistance, taking about three milliamperes at the given voltage, was connected across the generator and the amplifier input connected to a four-dial resistance box in the tail circuit. For this work a negative input grid bias of about three volts was used and the input so connected as to make the input potential more positive for increased applied voltages. The distance between "1" and "2" on Fig. 14 represents 5800 volts. Thus the oscillographic study was made very easily at a number of different voltages with the amplifier, which would have been very troublesome otherwise.

## CONCLUSION

It was the purpose of this work to develop a simple and convenient method for making oscillographic studies of high-voltage and low-current waves and similar phenomena—one which could be depended upon to give perfect reproduction of very small currents, preserving them in their true phase relations as well as in form. It is felt that this has been accomplished and that the amplifying oscillograph, if the combined amplifier and oscillograph may be so called, should prove a useful instrument in electrical engineering research. The oscillograph, already valuable in a wide field, has now had its range extended down to currents of about ten microamperes or less.

## ACKNOWLEDGMENT

The author wishes to acknowledge his indebtedness to the Department of Electrical Engineering of the Johns Hopkins University for the use of its apparatus and laboratory where this development has been accomplished. He also wishes to express his appreciation to those at the University who have shown interest in the progress of the work and who have made suggestions from time to time.
